# CHAPTER 1

## INTRODUCTION AND OUTLINE OF THE THESIS

### • Human Genetic Susceptibility to Infectious Diseases

Infectious diseases are a major cause of human morbidity and mortality worldwide and, despite great advances in human medicine and genomics, they remain so, particularly in low income countries and in young children<sup>1,2</sup>. A main feature of human infectious diseases is that only a proportion of the individuals exposed to an infectious agent will actually develop disease, suggesting that genetic and health factors determine susceptibility to infectious diseases. Heritable factors were long considered to play a determining role in infectious studies and since 1923 the role of heredity has been studied by Webster and others using mice<sup>3</sup>. Indeed, single-gene (Mendelian) disorders leading to primary immuno-deficiencies, although often rare, provided the first information on the role of genetics in determining susceptibility to infectious diseases. The best-known, relatively common, single-gene disorder that influences susceptibility to infection is the sickle cell heterozygosity against falciparum malaria<sup>4</sup>. Further clues came from early twin studies, which provided significant evidence on the role of human host genetic factors in diseases such as leprosy, poliomyelitis, hepatitis B, tuberculosis and *Helicobacter pylori* infection<sup>5-11</sup>. In addition, follow-up studies of adopted children in the late 1980s showed they had a markedly increased risk to death from infection if one of the biological parents had died prematurely from an infection rather than other causes such as cancer or cardiovascular diseases<sup>12</sup>. Thus, an important role for host genetics in determining susceptibility to infectious diseases has been well established.

Moreover, genome-wide linkage studies provided further evidence of the role of genetics in infectious diseases, including *Schistosoma mansoni*, *H. pylori* and leprosy<sup>13-17</sup>. However, the main disadvantage of linkage studies is that it is difficult to recruit sufficient numbers of sibling pairs affected by the same infection. Thus, these studies are not sensitive enough to detect genes with a relatively small effect size that are characteristic for infectious diseases.

**Linkage studies:** Studies aimed at establishing linkage between genes. Linkage is the tendency of genes and genetic markers that are close together on a chromosome to be inherited together. These studies usually involve large families where the disease affects individuals in several generations.

**Sibling pairs:** Sibling pairs affected with the disease of interest are often the design of choice in linkage analysis studies with the aim to identifying genes that increase susceptibility to complex diseases. Such a design has the advantage of making few assumptions about the mode of inheritance of the disease.

- **Studying the Genetics of Infectious Diseases: What's New**

Recent advances, such as a map of human genetic variation compiled by the international HapMap project<sup>18</sup> and the 1000 Genomes project<sup>19</sup>, the application of genome-wide associations studies (GWAS) together with imputation tools (see *chapter 5*) and the development of new sequencing platforms, have all contributed to a better understanding of genetics in various human complex diseases. Such attempts have also focused on infectious diseases, although GWAS to identify genetic risk factors for these have not been as successful as in other complex diseases, such as immune-mediated diseases (Fig. 1A). As shown in Figure 1, there is a lack of genetic information for infectious diseases despite the fact that genetic variants associated with infectious diseases increase risk by 2-3 fold, an order of magnitude higher than observed for other complex diseases (Fig. 1B).

**Genome-wide association study (GWAS):** It is an approach that involves the genotyping of a genome-wide set of genetic variants in many individuals to find genetic variations associated with a particular disease. Such an approach is particularly useful in finding associations between single-nucleotide polymorphisms (SNPs) and common, complex diseases.

One of the major limitations in studying the genetics of infectious diseases is the lack of power due to small patient cohorts. The collection of such a cohort is complicated by the possible presence of co-morbidities in infected patients. Moreover, the use of appropriate controls is challenging as it is often unclear whether individuals have been exposed to the infectious agent due to the presence of asymptomatic infections. In addition to sufficient sample sizes and appropriate controls, another limitation of GWAS alone is that we cannot functionally interpret the identified associations and therefore need functional validation of novel findings from *in vitro* and/or *in vivo* experimental models.

Yet another limitation of studying infectious diseases stems from the emergence of an infectious disease, which is in principle the result of interaction by three main factors: pathogen, environment and human host genetics. Therefore, to better understand how individuals become infected, we need to capture this interaction but classical GWAS studies can detect only the genetic component. We require novel approaches to address the challenges of studying infectious diseases and highly integrated research that will offer a better understanding of the complex interplay between host, invading pathogen and environment. To this end, the development of high-throughput technologies, which allow us to collect multi-omics data (Table 1), together with advanced computational methods, has opened new opportunities to successfully implement a systems genomics approach. Instead of studying individual molecular components that contribute to a disease, we can

now generate and integrate high-throughput multi-omics data (genomics, transcriptomics, proteomics) in the context of the disease, which capture the dynamic interactions between pathogen-host-environment. In the next section, we will discuss the use of a systems genomics approach in the field of infectious diseases.

## • Systems Genomics Approach to Studying Host-Pathogen Interactions

Cancer research was one of the first fields to embrace the use of a systems genomics approach<sup>20</sup>. In response to the need for new approaches, the National Institute of Allergy and Infectious Diseases (NIAID, <https://www.niaid.nih.gov/>) has sponsored the Systems Biology Programme for Infectious Disease Research<sup>21</sup>. This programme consists of four centres, each of which focuses on studying interaction between the human host and a different bacterial or viral pathogen, including *Mycobacterium tuberculosis* bacillus, H5N1 avian influenza virus, and severe acute respiratory syndrome-associated coronavirus (SARS-CoV), influenza virus strains of various pathogenicities, *Salmonella enterica* serovar Typhimurium and *Yersinia* species.

One of the main advantages of a systems genomics approach is that multiple phenotypes, such as gene and protein expression data, can be collected for a reference population and subsequently associated with genetic variation. Using this

**Fig. 1.** (A) Number of genetic associations identified in genome-wide association studies (GWAS) with  $P$  value  $< 1 \times 10^{-6}$ , as recorded in the GWAS catalogue so far (<https://www.ebi.ac.uk/gwas/>), for a number of common immune-mediated and infectious diseases. (B) Effect size (odds ratio, OR) of immune-mediated diseases versus infectious diseases, extracted from the GWAS catalogue (<https://www.ebi.ac.uk/gwas/>).

### Box 1. Brief description of fungal pathogens

***Candida albicans*.** Currently, there are 200 species in the genus *Candida*. These are collectively responsible for as many as 400,000 cases of systemic fungal diseases per year worldwide, with mortality rates of up to 40%<sup>34–37</sup>. The limited arsenal of anti-fungal drugs, which are classified into three classes, and the emergence of drug resistance through multiple mechanisms, including the formation of biofilms, make *Candida* the fourth most common cause of nosocomial infections<sup>38–44</sup>. Of these species, *Candida albicans* (*C. albicans*) is one of the best studied and most prevalent of the human fungal pathogens<sup>45</sup>. It is an opportunistic pathogen and, under physiological conditions, resides in the gut, genito-urinary tract and skin. Infection occurs only if the epithelial barrier function is impaired and/or there are microbiome imbalances and/or the host's immune system is compromised. It is generally believed that the main reservoir for *C. albicans* in humans is in the gastrointestinal tract and, once this barrier is disrupted, *C. albicans* can cause systemic infections<sup>46,47</sup>.

Under pathogenic conditions, it can lead to superficial infections of the skin up to severe mucosal or life-threatening systemic infections, with the latter being associated with high mortality rates. One of the critical properties that determines the virulence of *C. albicans* is the phenotype switching between unicellular yeast cells and filamentous forms, called hyphae or pseudohyphae, which is known as morphological dimorphism (Fig. 2)<sup>48,49</sup>. This fungal dimorphism facilitates invasion of host tissues, escape from macrophages, dissemination in the bloodstream, and differentially affects immune recognition<sup>50,51</sup>. *C. albicans* is able to switch morphology in response to various environmental triggers, including a rise in temperature to 37°C, a pH equal to or higher than 7.0, a CO<sub>2</sub> concentration of 5.5% or the presence of serum or carbon sources, which stimulate hyphal growth<sup>52,53</sup>. Hyphae forms cause tissue damage and invasion, whereas yeast cells are thought to be responsible for dissemination to the environment and to new hosts<sup>54</sup>.

***Aspergillus fumigatus*.** *Aspergillus fumigatus* (*A. fumigatus*) is the most prevalent airborne, filamentous, saprophytic and ubiquitous fungus responsible for mould. It is found worldwide and its conidia have a small diameter of 2–3 µm; they are abundant in the normal environment<sup>55</sup>. Everyone can inhale airborne *A. fumigatus* conidia, because their concentration in air is high (approx. 1–100 conidia per m<sup>3</sup>)<sup>56</sup>. Upon inhalation, the fungus penetrates alveolar epithelial and endothelial cells before an effective adaptive immune response is mounted against the fungus<sup>57</sup>. Depending on the host's immune status, this fungus can cause a range of pulmonary diseases, including allergic, invasive and non-invasive diseases. These diseases include *invasive pulmonary aspergillosis* (IPA), which is a severe disease characterized by tissue destruction, primarily affecting patients with severe immunodeficiency, but also critically ill patients without neutropenia and patients with chronic obstructive pulmonary disease (COPD)<sup>58,59</sup>. *Chronic pulmonary aspergillosis* includes aspergilloma and progressive destructive cavitary disease (also known as *chronic necrotizing pulmonary aspergillosis*)<sup>58,59</sup>. Aspergilloma is a fungus ball that usually develops in a patient's body cavity such as a paranasal sinus or an organ such as the lung; it is occasionally complicated by life-threatening haemoptysis. *Chronic necrotizing aspergillosis* is a locally invasive disease that mainly affects patients with chronic lung disease or mild immunodeficiency<sup>59</sup>. *Allergic bronchopulmonary aspergillosis* (ABPA) is a non-invasive form of lung disease that includes a hypersensitivity reaction to *Aspergillus* antigens; it is exclusively seen in patients with asthma or cystic fibrosis<sup>59</sup>.

***Cryptococcus neoformans*.** *Cryptococcus neoformans* (*C. neoformans*) is a saprophytic, basidiomycetous, dimorphic organism found worldwide; its natural habitats are pigeon droppings and contaminated soil. Small-sized basidiospores (1.8 to 3.0 µm in diameter)<sup>60,61</sup> can form yeast cells, which are favoured at 37°C, or dikaryotic hyphae, favoured at 24°C<sup>53</sup>. When humans inhale basidiospores or yeast cells, the pathogen can disseminate throughout the respiratory tract leading to pulmonary infections. In some rare cases, *C. neoformans* can also infect the central nervous system leading to life-threatening meningoencephalitis, in both immuno-compromised and immuno-competent patients. If meningoencephalitis is left untreated, it is always fatal, while even after treatment the mortality rate lies between 10–25%<sup>60,62</sup>.

approach, known as quantitative trait loci (QTL) mapping, genetic variants that regulate a given phenotype can be identified. In this way, we can connect phenotypes with genes and gene networks that better reflect the complex nature of host-pathogen interactions. For instance, genetic variants that influence gene or protein expression in close proximity to the gene of interest are known as *cis*-expression quantitative trait loci (eQTLs) or *cis*-protein quantitative trait loci (pQTLs). When genetic variants affect gene expression or protein levels in a distal manner, they are known as *trans*-eQTLs or *trans*-pQTLs. Importantly, it has been found that some diseases showed marked cell-type specificity, which means that genetic variants associated with a certain disease are enriched for cell-type-specific *cis*-eQTLs<sup>22,23</sup>. Furthermore, a systems genomics approach is a hypothesis-free approach, which can reveal novel, previously unknown associations. In general, studies of infectious diseases in humans are compromised because of patients' uncertain history of lifetime infections and the pathogens involved; moreover, experimental infection in volunteers is performed to a very limited extent for obvious ethical reasons. Therefore, another advantage of using a systems approach in infectious diseases is that we can generate and integrate molecular data from *in vitro* (cell lines, stem cells, etc.) and *in vivo* experimental models (animal models) and translate the results into a clinical situation by predicting disease outcome in human patients. For instance, in the case of influenza in which the responses in mice are very similar to those in human and non-human primates, the experimental animal models represent excellent systems for using systems biology to gain a comprehensive understanding of influenza-host interactions<sup>24</sup>.

Thus, in the last few years, we have witnessed how the study of host-pathogen interactions during infection has moved towards implementing a systems approach. In this thesis, my aim is to identify risk genes and molecular pathways underlying the immune defence to infectious diseases by implementing a systems genomics approach. My main focus has been on fungal diseases, particularly those caused by the opportunistic fungal pathogen *Candida albicans* (*C. albicans*). Next, I describe what is currently known about genetics and immune defence mechanisms during *C. albicans* infections and provide an outline of the thesis chapters.

---

## • Why Do We Study Fungal Diseases?

---

Fungal diseases kill more than 1.5 million people worldwide every year and affect over a billion people<sup>25</sup>. In recent decades, the problem of severe nosocomial fungal diseases has become more serious, especially in immune-compromised patients. The risk factors for developing fungal diseases have been well-described<sup>26</sup>, although not all at-risk patients will develop disease, suggesting that host genetics also determines susceptibility to fungal infections. Although the epidemiology of fungal diseases has changed greatly over the past few decades, the most frequently diagnosed fungal infections are caused by

**Fig. 2.** Forms of *Candida albicans*. *C. albicans* is referred to as dimorphic fungus since it grows as round yeast cells and as filamentous cells known as hyphae of pseudo hyphae, depending on the micro-environment.

Picture adapted from: <http://www.usask.ca/biology/kaminskyj/images/BachewichCandida.jpg>, University of Saskatchewan, Canada

pathogens from the genera *Candida*, *Cryptococcus* and *Aspergillus*<sup>27</sup> (Box 1). These fungi are ubiquitous and, in particular, *Cryptococcus neoformans* (*C. neoformans*) and *Aspergillus fumigatus* (*A. fumigatus*) can be found in the host environment, whereas *Candida albicans* (*C. albicans*) is part of the normal microbiota of an individual's skin, mucocutaneous surfaces and gastro-intestinal tract<sup>28</sup>. *C. albicans* is the main cause of mucosal and systemic infections, *A. fumigatus* of most allergic fungal diseases, and *C. neoformans* of lung diseases that may spread to the brain and cause meningoencephalitis. Diagnosing a fungal infection is often difficult due to the presence of non-specific symptoms, while challenges in isolating and identifying fungi make it ineffective to prevent and treat these infections<sup>29,30</sup>. There are no vaccines available and, despite the availability of potent antifungal drugs, fungal diseases have a high mortality, estimated at 1.5 million annually<sup>25</sup>. In addition, identifying novel drug targets and developing effective antifungal drugs is complicated by the similarity between eukaryotic fungi and humans.

*C. albicans* is considered to be the major fungal pathogen of humans in the heterogeneous group of *Candida* species (Box 1, Fig. 2)<sup>31</sup>. It is an opportunistic fungus that is potentially pathogenic when the immune system is weakened causing superficial or systemic infections (candidaemia). Several risk factors are known to increase the risk of developing *Candida* infections, including a prolonged stay in intensive care (ICU), use of immunosuppressive agents/antibiotics, transplantation, surgical intervention, neutropenia, solid tumour and haematological malignancies, and parenteral nutrition<sup>32</sup>. Although these factors are important, they do not explain all *Candida* infections and only a minority of patients at risk will actually develop disease, suggesting the critical role of genetics in determining

disease susceptibility. Indeed, several monogenetic disorders that result in severe primary immunodeficiencies, and mutations and common polymorphisms in immune genes, have been associated with an increased susceptibility to mucosal and/or invasive *Candida* infections (Box 2).

**Box 2. Genetic susceptibility to *Candida* infection.** Several monogenetic disorders have been linked to increased susceptibility to both mucosal and systemic *Candida* infections. These disorders have mutations in immune genes, such as *CARD9*, *STAT1*, *IL-23* and *IL-22* as heterodimer with *STAT3* or *STAT4*, *STAT3*, *IL-17A*, *IL-17F*, dedicator of cytokinesis (*DOCK*)8 and *TYK2*; they have been reviewed in detail elsewhere<sup>63</sup>. Patients carrying mutations in genes coding for cytokines and their receptors, such as *IL-12RB1* and *CD25*, also have an increased susceptibility to *Candida* infections<sup>64</sup>. Moreover, an increased susceptibility to *Candida* (both mucosal and systemic infections) can also be explained by the presence of common polymorphisms mainly in genes that encode cytokines and receptors that recognize fungal antigens, such as *Dectin-1*, *TLR-1*, *TLR-2*, *TLR3*, *TLR-4*, *MBL-2*, *IL-4*, *IL-10*, *IL-12b*, *DEFB1*, (coding for beta-defensin 1), *PTPN22* and *NLPR3*<sup>63</sup>. Lastly, a genome-wide screen of approximately 200,000 SNPs in 186 loci recently identified three more genes (*CD58*, *LCE4A-C1orf68* and *TAGAP*) associated with candidaemia susceptibility<sup>65</sup>.

Despite significant progress over the last few years in identifying susceptibility genes for *Candida* infections, there is still much genetic information unexplored and particularly the molecular mechanisms underlying susceptibility are not fully understood. Both innate and adaptive immune responses are important for host immune defence against fungal pathogens (Box 3).

However, it is difficult to identify genetic factors using a traditional GWAS because of the limited size of patient cohorts and use of inappropriate controls (such as individuals with asymptomatic infections). In the case of invasive *Candida* infections, it is difficult to gather large cohorts of patients, as they are relatively scarce, especially in individual medical centres. In addition, a GWAS alone cannot explain how genetic variation affects disease or which organ or tissue, or even which cell type, will be affected. To overcome these challenges, we use a systems genomics approach to identify risk loci and molecular pathways underlying host immune defence and disease pathogenesis. In particular, to investigate the effect of *Candida* infection on host immune response, we explore changes at the transcriptomic or proteomic level in a relevant mixture of lymphocytes (T cells, B cells, and NK cells) and monocytes, i.e. in peripheral blood mononuclear cells (PBMCs), which are easily available. By integrating different molecular data (genomics, transcriptomics, proteomics and immunological data), we aim to gain a better understanding of the host immune defence mechanisms against *C. albicans* (Fig. 3). In the next section, I present an outline of this thesis.

**Box 3. Immune defence against *Candida* fungal infections.** The innate immune system forms the first line of defence against all invading organisms. Its first response involves recognizing invading fungi from immune cells, such as phagocytes, via specialized receptors that recognize conserved pathogen-associated molecular patterns (PAMPs), which are known as pattern recognition receptors (PRRs)<sup>66–68</sup>. This recognition induces signalling-mediated gene transcription that leads to the secretion of inflammatory proteins, such as chemokines and cytokines<sup>66–68</sup>. In turn, the inflammatory proteins recruit neutrophils and other immune cells to the infection site, killing the fungal cells and activating the adaptive immune responses<sup>66–68</sup>.

Neutrophils play a pivotal role in controlling fungal infections, with neutropenia being a major risk factor for invasive fungal infections<sup>69,70</sup>. These cells kill *Candida* cells through phagocytosis, oxidative and non-oxidative effector mechanisms, and the release of neutrophil extracellular traps (NETs)<sup>71–73</sup>. The PRRs include the well-known Toll-like receptors (TLRs; TLR2 and 4), C-type lectin receptors (CLRs, such as dectin-1, dectin-2 and mannose receptor (MR)), NOD-like receptors (NLRs), and RIG-I-like receptors (RLRs)<sup>74</sup>.

The fungal PAMPs mainly consist of polysaccharides that are present on the fungal cell wall. Of note, the polysaccharide structures differ between yeasts and hyphae of *C. albicans*, which can explain the differential immune responses reported between the two forms of *C. albicans*<sup>50,75–81</sup>. As a crucial part of the innate immune response, early studies showed that *C. albicans* activates the complement system via all three pathways (the classical, the alternative and the lectin pathway)<sup>82–85</sup>. The interaction of *C. albicans* with the complement system has been reviewed in detail<sup>86</sup>. Activation of the complement system by *C. albicans* contributes to the enhanced induction of pro-inflammatory cytokines in PBMCs, such as IL-6 and IL-1 $\beta$ , by the activation of the anaphylatoxin C5a<sup>87</sup>. In an attempt to escape the immune surveillance, *C. albicans* has been shown to bind two central complement regulator factors, H and FHL-1, from human serum and it thus escapes the control of the complement system<sup>88</sup>. Platelets are less appreciated players of the host immune defence, despite the fact that the interaction of *C. albicans* with platelets has been reported in early *in vitro* and *in vivo* studies<sup>89–91</sup>. Platelet-rich plasma presents anti-microbial peptides with anti-candida activity, such as the chemokine RANTES, platelet-factor-4 (PF-4) and thrombospondin-1 (TC-1), and it also inhibits candida growth<sup>92–94</sup>.

## • Outline of the Thesis

In *chapter 2*, we demonstrate the potential of using a systems genomics approach to identify genes and pathways underlying susceptibility to *Candida* infection. In this study, we integrated genetic data from our candidaemia patient cohort with gene-expression profiles recorded upon *Candida* stimulation in PBMCs isolated from eight healthy volunteers, *Candida*-induced cytokine production capacity in PBMCs (TNF $\alpha$ , IL-6 and IFN $\gamma$ ), and circulating concentrations of three pro-inflammatory cytokines (IL-6, IFN $\gamma$  and IL-8) in patient serum. Our candidaemia cohort consisted of 217 patients of European ancestry and genotyped with the Immunochip SNP array that covers 186 loci<sup>33</sup>. For association testing, we followed a two-stage analysis and used two different control groups: 11,920 population-based healthy controls in the first stage and 146 case-matched but candidiasis-free controls in the second stage (Table 2). By integrating all these different datasets, we could prioritize genes from the Immunochip study and investigate the pathways in which these genes are enriched. Lastly, we followed up a gene from one of the

**Fig. 3.** A systems genomics approach towards understanding the interactions of *C. albicans* with its human host. To identify risk loci and pathways to *Candida* infection, we integrate different molecular data (from left to right): (1) Genome-wide genetic data generated from our candidaemia cohort that was used for the GWAS. (2) To study how the gene immune responses are modulated by *Candida* infection, we used RNA sequencing to generate expression data from PBMCs stimulated by *C. albicans*. (3) To further investigate response modulation by *Candida* infection, we measured the inflammatory responses from PBMCs stimulated by *C. albicans*. By using genetic data and expression data or measurements of inflammatory proteins, we were able to map the genetic variation that influences gene expression or inflammatory proteins, respectively, i.e. expression-quantitative trait loci (eQTLs) or protein-QTLs (pQTLs). Our ultimate goal is to prioritize good candidates genes for follow-up *in vitro* and *in vivo* functional experiments, leading to a better understanding of their role in human immune defence against *C. albicans*.

candidaemia-associated loci (*MAP3K8*) with *in vitro* experiments to validate its role in cytokine regulation in response to *Candida* infection.

In chapter 3, we first describe exploring the genetic architecture of cytokine responses induced by the two forms of *C. albicans* (yeast and hyphae). Then we extended our studies to the two other common fungal pathogens acquired from the environment (*A. fumigatus* and *C. neoformans*) and investigated the hypothesis that susceptibility to candidaemia is explained by modulating the levels of pro-inflammatory cytokines. To identify genetic loci that regulate cytokine responses in response to stimulation with these three opportunistic fungi, we made use of genetic data and measurements of six cytokines (IL-6, TNF $\alpha$ , IL-1 $\beta$ , IL-17,

IL-22 and IFN $\gamma$ ) from a large, population-based cohort of European ancestry, the 500 Human Functional Genomics (500FG) cohort (Human Functional Genomics Project, HFGP, see [www.humanfunctionalgenomics.org](http://www.humanfunctionalgenomics.org)). Using these data, we mapped genetic variation that influences cytokine levels, i.e. cytokine-quantitative trait loci (cQTLs). cQTL studies can offer mechanistic insight into how genetic variation can affect disease and, thus, help in prioritizing genes that potentially cause disease. The measured cytokines were derived from three different cell systems (PBMCs, whole blood and monocyte-derived macrophages) stimulated by the three fungi (Table 2). Since the ImmunoChip SNP array covers only 3% of the genome, we went on to perform the first GWAS to date to identify novel susceptibility loci in our candidaemia patient cohort (Table 2) and to explore whether genetic variants that influence cytokine levels are also associated with susceptibility to candidaemia.

With the aim of systematically exploring the inflammatory proteins released into the blood circulation upon *Candida* stimulation, we extended our studies in *chapter 4* by profiling 92 inflammatory proteins in plasma from our candidaemia patient cohort ( $n = 42$ ) and from healthy individuals in the Lifelines cohort (<https://www.lifelines.nl/researcher/biobank-lifelines/>) ( $n = 89$ ), and also in *Candida*-stimulated PBMCs from two independent population-based cohorts, the 500FG ( $n = 360$ ) and Lifelines DEEP cohort (<https://www.lifelines.nl/researcher/biobank-lifelines/additional-studies/lifelines-deep>) ( $n = 76$ ), using the high-throughput technology OLINK (<https://www.olink.com/>). Using genetic data and protein measurements from the 500FG and Lifelines DEEP cohorts, we investigated the genetic factors that determine inflammatory responses in the context of *Candida* infection by performing genome-wide protein-quantitative-trait loci (pQTL) mapping. We also checked whether genetic variation influencing inflammatory responses could explain susceptibility to candidaemia and survival outcome among candidaemia patients. Table 2 describes the cohorts, technologies and molecular data that we generated in the context of *Candida* infection for this PhD research.

In *chapter 5*, we focus on the major histocompatibility complex (MHC) locus, also known as the human leukocyte antigen (HLA), as it plays an important role in recognition of pathogenic antigens during host immune defence and it has been reported as a major risk factor for complex diseases. We review recent advances that have contributed to a better understanding of the role of MHC in two major classes of complex diseases: autoimmune and infectious diseases. Of note, we compare the associations reported so far for autoimmune and infectious diseases and discuss the role of pathogens in autoimmune disease development.

Lastly, in *chapter 6*, we discuss the challenges of studying the genetics of infectious diseases, what we have learned from using a systems genomics approach in *Can-*

*did*a infection and the limitations of our work. We also describe our findings in a broader perspective and future directions for studying the genetics of infectious diseases. In summary, we aimed to implement a systems genomics approach to reveal the genetic architecture and molecular pathways that underlie susceptibility to candidaemia. By integrating different layers of molecular data, our ultimate goal was to pinpoint and prioritize genes that could serve as potential immunotherapeutic targets to improve patient outcome (Fig. 3). Importantly, we aimed to provide a framework to identify genes and molecular pathways not only for candidaemia, but also for other infectious diseases.

**Table 2.** Summary of the cohorts and molecular data used in this thesis.

Genetic data						
Candidaemia cohort	Number of individuals	Genotyping array	Imputation	Chapter		
Immunochip-wide association analysis						
Cases	217 (European ancestry)	Immunochip (Illumina)	no	2		
Controls (population-based)	11,920 (European ancestry)	Immunochip (Illumina)	no	2		
Controls (case-matched)	146 (European ancestry)	Immunochip (Illumina)	no	2		
GWAS						
Cases	178 (Europeans) of which 31 non-surv.** ( Days < 14) 18 non-surv.** ( 14 < Days < 30 ) 16 non-surv.** ( 30 < Days < 90 ) 83 survivors	HumanCoreExome-24 v1.0 and HumanCoreExome-12 v1.0 (Illumina)	yes (HRC*)	3 4 4 4 4		
Controls (case-matched)	175 (European ancestry)	HumanCoreExome-24 v1.0 and HumanCoreExome-12 v1.0(Illumina)	yes (HRC*)	3		
Population-based cohorts						
200FG	~200 healthy individuals (Europeans)	ImmunoChip (Illumina)	yes (HRC*)	3		
500FG	534 healthy individuals (Europeans)	Illumina Human OmniExpress Exome-8 v1.0	yes (GoNL***)	3, 4		
Lifelines Deep	1539 healthy individuals (Europeans)	CytoSNP, ImmunoChip (Illumina)	yes (GoNL***)	4		
Transcriptomic data						
Cohort	Cell system	Stimulation time	Stimulant	Technique	Chapter	
8 healthy volunteers	PBMCs	4 and 24 hours	C. albicans yeast	RNA sequencing	2	
Cytokine data						
Cohort	Cell system	Cytokines	Stimulation time	Stimulant	Technique	Chapter
Healthy volunteers	PBMCs	TNFα, IL-6	1 day	C. albicans yeast	ELISA	2
Healthy volunteers	PBMCs	IFNγ	2 days	C. albicans yeast	ELISA	2
Candidaemia patients	serum	IL-6, IL-8, IFNγ			ELISA	2
500FG	macrophages	IL-6, TNFα	1 day	C. albicans yeast	ELISA	3
500FG	PBMCs	IL-6, TNFα, IL-1β	1 day	C. albicans yeast	ELISA	3
500FG	blood	IL-6, TNFα, IL-1 β,IFNγ	2 days	C. albicans yeast	ELISA	3
500FG	PBMCs	IL-17, IL-22, IFNγ	7 days	C. albicans yeast	ELISA	3
500FG	PBMCs	IL-6, TNFα, IL-1 β	1 day	C. albicans hyphae	ELISA	3
500FG	PBMCs	IL-17, IL-22, IFNγ	7 days	C. albicans hyphae	ELISA	3
500FG	PBMCs	IL-6, TNFα	1 day	A. fumigatus	ELISA	3
500FG	PBMCs	IL-17, IL-22, IFNγ	7 days	A. fumigatus	ELISA	3
500FG	PBMCs	IL-6, TNFα, IL-1 β	1 day	C. neoformans	ELISA	3
500FG	PBMCs	IL-17, IL-22, IFNγ	7 days	C. neoformans	ELISA	3
500FG (n = 360)	PBMCs	92 inflammatory proteins	1 day	C. albicans yeast	OLINK	4
Lifelines Deep (n= 76)	PBMCs	92 inflammatory proteins	1 day	C. albicans yeast	OLINK	4
Lifelines (n = 89)	plasma	92 inflammatory proteins			OLINK	4
Cases (n = 42)	plasma	92 inflammatory proteins			OLINK	4

## Abstract

Candidaemia is a bloodstream infection caused by *Candida* species that primarily affects specific groups of at-risk patients. Because only small candidaemia patient cohorts are available, classical genome wide association cannot be used to identify *Candida* susceptibility genes. Therefore, we have applied an integrative genomics approach to identify novel susceptibility genes and pathways for candidaemia. *Candida*-induced transcriptome changes in human primary leukocytes were assessed by RNA sequencing. Genetic susceptibility to candidaemia was assessed using the Illumina immunoChip platform for genotyping of a cohort of 217 patients. We then integrated genetics data with gene-expression profiles, *Candida*-induced cytokine production capacity, and circulating concentrations of cytokines. Based on the intersection of transcriptome pathways and genomic data, we prioritized 31 candidate genes for candidaemia susceptibility. This group of genes was enriched with genes involved in inflammation, innate immunity, complement, and hemostasis. We then validated the role of *MAP3K8* in cytokine regulation in response to *Candida* stimulation. Here, we present a new framework for the identification of susceptibility genes for infectious diseases that uses an unbiased, hypothesis-free, systems genetics approach. By applying this approach to candidaemia, we identified novel susceptibility genes and pathways for candidaemia, and future studies should assess their potential as therapeutic targets.

## Introduction

Genome-wide association studies (GWAS) have greatly contributed to the identification of susceptibility genes for human complex diseases. However, the need for large cohorts

grant [863.13.011 to Y.L.]. V.M. is supported by a PhD scholarship from Graduate School of Medical Sciences, University of Groningen, the Netherlands. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

**Competing interests:** The authors have declared that no competing interests exist.

precludes the use of GWAS to identify susceptibility genes for infectious diseases for which only relatively small patient cohorts can be recruited. So far, relatively few GWAS studies have been performed in patients with infections, including studies of viral and bacterial infections [1]. Compared to the hundreds of genetic loci that have been associated to human complex diseases, the number of susceptibility genes identified as associated to infectious diseases remains low. Given that the risk of death due to infectious diseases has a large genetic heritability [2], methods other than GWAS that can be applied to smaller cohorts are crucial to make progress in understanding and treating these diseases.

Candidaemia is the fourth most common systemic bloodstream infection in the United States (US) and is associated with mortality rates of up to 40% [3,4]. It is caused by opportunistic fungal pathogens belonging to the *Candida* species, particularly *Candida albicans* (*C. albicans*), and primarily affects patients with a compromised immune system [5]. However, not all at-risk patients develop candidaemia, indicating that individual differences—including genetic background—influence their susceptibility to the infection. Despite the availability of potent antifungal drugs, the mortality rate of systemic *Candida* infections remains unacceptably high [6]. In addition to current treatment strategies, only adjuvant immunotherapy such as the administration of recombinant cytokines is believed to improve outcome [7]. Therefore, an understanding of the molecular pathways involved in the human host defence and identification of susceptibility genes is crucial for the design of appropriate prophylactic and immunotherapeutic strategies.

To identify genes underlying susceptibility to *Candida* infection, we have applied a systems genomics approach that integrates genetic data from candidaemia patients genotyped with the Immunochip platform [8] with *Candida*-induced gene-expression profiles in human leukocytes, cytokine production from *Candida*-stimulated peripheral blood mononuclear cells (PBMCs), and circulating cytokine concentrations in candidaemia patients. Using this approach, we demonstrate that genetic susceptibility loci with suggestive associations ( $P < 9.99 \times 10^{-5}$ ) could play a major role in candidaemia susceptibility and we identify genes involved in inflammation, innate immunity, complement and hemostasis as having an important role in determining susceptibility to candidaemia.

## Materials and methods

### Study populations

To identify genetic variants associated with candidaemia, we performed a two-stage Immunochip-wide analysis of a candidaemia cohort using two control groups in 2014: a population-based healthy cohort and disease-matched cohort (European ancestry), as previously described [9]. Briefly, for Immunochip-wide association analysis, we first used a cohort consisting of 217 candidaemia patients of European ancestry and 11,920 population-based healthy controls (Discovery stage). The demographic and clinical characteristics of the candidaemia cohort have been previously described [9]. Re-analysis of the data and prioritization of genes from susceptibility loci with suggestive associations ( $P < 9.99 \times 10^{-5}$ ) was performed in 2017.

After the discovery of single nucleotide polymorphisms (SNPs) for susceptibility to candidaemia using population-based healthy controls, we then validated our findings using a validation control consisting of 146 disease-matched but candidiasis-free controls. These candidiasis-free control patients were recruited from the same hospital wards as the candidaemia patients so that co-morbidities and clinical risk factors for infection were as similar as possible between patients and controls.

## Ethics statement

The study was approved by the institutional review boards at each study centre, and enrollment occurred between January 2003 and January 2009. The study centers are the Duke University Hospital (DUMC, Durham, North Carolina, USA) and Radboud University Nijmegen Medical Centre (Nijmegen, The Netherlands). All adult subjects provided informed written consent.

## Genotyping and case-control analysis of candidaemia cohort

DNA was isolated using the Gentra Pure Gene Blood kit (Qiagen, Venlo, the Netherlands) according to the protocol of the manufacturer. Genotyping of candidaemia patients and both control groups was performed using Immunochip according to Illumina's protocol [10]. Genotype data analysis and quality control of this cohort has been previously reported [9]. Briefly, in the discovery stage, the associations of Immunochip SNPs and susceptibility with candidaemia were tested by logistic regression using the first four components from the multidimensional scaling analysis as covariates. We considered a P value  $< 9.99 \times 10^{-5}$  as the threshold for suggestive association to select 268 SNPs in 77 independent loci for validation. For validation analysis using candidaemia case-matched controls, the association between SNPs and candidaemia was tested by logistic regression using the first four multidimensional scaling analysis components as covariates. A validation P value  $< 0.05$  was considered significant.

## PBMC isolation and stimulation with *Candida albicans*

Isolation of PBMCs from eight healthy volunteers and stimulation of PBMCs was performed as described previously [11]. After cell counting with a hemocytometer, the cell number was adjusted to  $5 \times 10^6$ /mL. To identify the transcriptome upon *Candida* stimulation,  $5 \times 10^5$  isolated PBMCs were incubated with  $1 \times 10^6$ /mL heat-killed *C. albicans* (UC 820) (*C. albicans*: PBMC ratio of 1:2.5) and RPMI culture medium as a control for 4 and 24 hours. *C. albicans* UC 820 is a well-described strain regarding its immune responses in PBMCs [12].

## Analysis of RNA sequencing reads

The RNA sequencing analysis of this dataset was described previously [13]. Briefly, sequencing reads were mapped to the human genome using STAR (version 2.3.0). The aligner was provided with a file containing junctions from Ensembl GRCh37.71. The Htseq-count of the Python package HTSeq (version 0.5.4p3) was used (<http://www-huber.embl.de/users/anders/HTSeq/doc/overview.html>) to quantify the read counts per gene based on annotation version GRCh37.71, using the default union-counting mode. Differentially expressed genes were identified by statistical analysis using the DESeq2 package. The statistically significant threshold (False Discovery Rate  $P < 0.05$  and Fold Change  $\geq 2$ ) was applied.

## Pathway enrichment analysis

We performed gene enrichment analysis using ConsensusPathDB-human database (CPDB; <http://cpdb.molgen.mpg.de/>) [14]. The over-representation analysis is done using the default setting in which the database compares the predefined lists of functionally associated genes (pathways and Gene Ontology categories) to the list of differentially expressed genes and generates P values based on the hypergeometric test. The hypergeometric test P values are further corrected for multiple testing using the false discovery rate method.

### MAP3K8 inhibition of cytokines in *Candida*-stimulated PBMCs

PBMCs ( $5 \times 10^5$ ) were placed in 96-well round-bottom plates in a final volume of 200  $\mu$ L. PBMCs were stimulated with ( $1 \times 10^6$ /mL) heat-inactivated conidia of *C. albicans* in the presence or absence of variable concentrations (10  $\mu$ M, 50  $\mu$ M, and 200  $\mu$ M) of a MAP3K8 inhibitor (#5240, Tocris Cookson Ltd., Bristol, UK) or a vehicle (DMSO) control. PBMCs were stimulated for 24 or 48 hours at 37°C and 5% CO<sub>2</sub>. After stimulation, culture supernatants were collected and stored at -20°C until cytokine assays were performed. Cytokine levels from *Candida*-stimulated PBMCs were measured in cell culture supernatants using enzyme-linked immunosorbent assay (ELISA) according to the manufacturer's instructions (R&D Systems, MN, USA). Differences in cytokine levels were compared for statistical significance using the Wilcoxon rank test.

## Results

### *Candida albicans* induces transcription of genes involved in inflammation and immune-hemostasis interaction

In our experiments, we have used heat-killed *C. albicans* instead of live *C. albicans* for two main reasons. The first one is that long incubation periods of more than 48 hours to obtain the T cell derived cytokines IL-17, IL-22 and IFN $\gamma$  result in overgrowth of the fungal cells and, ultimately, in cell lysis. Therefore, to achieve cell viability, we opted for heat-killed *C. albicans*. Secondly, the immune response is enhanced when using heat-killed *C. albicans* instead of live *C. albicans*. Heat-killing enhances the accessibility of  $\beta$ -glucans, whereas in live *C. albicans* yeast cells,  $\beta$ -glucans are shielded from immune recognition by a mannan layer. The  $\beta$ -glucans, which can be found in the inner layer of the *C. albicans* cell wall represent the main conserved pathogen-associated molecular patterns (PAMPs) that are recognized by one of the most important innate receptors for the recognition of *Candida* species, known as C-type lectin receptors (CLRs) [15]. The recognitions of  $\beta$ -glucans by CLRs constitutes the first step in the development of an immune response to *C. albicans*. Therefore, enhanced accessibility of  $\beta$ -glucans results in a pronounced immune response when using heat-killed *C. albicans* instead of live cells.

The transcriptome of PBMCs upon *Candida* stimulation was profiled by next-generation RNA sequencing (Fig 1). A total of 312 (4 hours) and 1,476 (24 hours) protein-coding genes were identified that showed >1.5-fold higher expression in cells stimulated with *C. albicans* compared to unstimulated cells (adjusted  $P < 0.05$ ) (S1 Table, S1A and S1B Fig). A total of 246 protein-coding genes were found to be more strongly induced both 4 h and 24 h after stimulation (S2 Table), while 66 genes showed increased expression after 4 h only and 1,230 genes were more strongly expressed after 24 h only.

Among the significantly differentially expressed genes, pathway enrichment analysis showed that there is an overrepresentation of genes involved in cytokine signalling and of chemokine genes at both 4 h and 24 h after stimulation. Pathway enrichment analysis on differentially expressed protein-coding genes confirmed previously described *Candida*-response pathways including cytokine signalling (4 h:  $P = 1.36 \times 10^{-12}$ , 24 h:  $P = 3.19 \times 10^{-9}$ ), Toll-like-receptor-mediated signalling [16] at 4 h ( $P = 0.00553$ ), interferon signalling [17] (4 h:  $P = 4.90 \times 10^{-10}$ , 24 h:  $P = 1.41 \times 10^{-5}$ ) and RIG-I/MDA5 mediated induction of IFN- $\alpha/\beta$  pathways (4 h:  $P = 7.55 \times 10^{-6}$ , 24 h:  $P = 0.00753$ ) (S3 and S4 Tables) [18]. The enrichment analysis also uncovered an overrepresentation of differentially expressed genes involved in dissolution of the fibrin clot at 4 h ( $P = 0.0018$ ) and 24 h ( $P = 0.00422$ ), alternative complement activation at 4h ( $P = 0.0022$ ), platelet activation, signalling and aggregation at 24 h ( $P = 0.0016$ ) and activation of C3 and C5 -a central step of complement activation- at 24h ( $P = 0.00479$ ). An even stronger effect for hemostasis ( $P = 6.51 \times 10^{-6}$ ) was observed at 24h (Figs 2

**Fig 1. Transcriptome of PBMCs upon *Candida* stimulation.** (A) Principal component analysis of RNA sequencing data obtained from eight healthy volunteers upon stimulation of their PBMCs with *C. albicans* for 4 or 24 hours or unstimulated. Four distinct groups were observed based on time-dependent exposure to *C. albicans* or culture medium alone using the first two principal components. Principal Component 1 (PC1, x-axis) represents 24% and PC2 (y-axis) represents 19% of total variation in the data. Green and red circles represent the stimulated samples with heat-killed *C. albicans* for 4 and 24 hours respectively and purple and blue circles represent the samples incubated with RPMI for 4 and 24 hours (used as controls) respectively.

<https://doi.org/10.1371/journal.pone.0180824.g001>

and 3). These results suggest that, along with genes involved in cytokine and interferon signalling, genes involved in the integration of immunity and hemostasis as biological processes may also be involved in the pathogenesis of systemic *Candida* infections.

### ImmunoChip-based genetic study identifies 18 candidaemia susceptibility loci

After identification of the transcriptome profile induced by *Candida* in human PBMCs, we explored whether these pathways could be validated through genetic association data from a clinical candidaemia cohort of 217 patients. We had previously reported three loci to be associated to *Candida* infection at genome-wide significance ( $P < 5 \times 10^{-8}$ ) by performing a case-control study on the ImmunoChip platform [9]. In addition to these three loci, during the discovery stage, we identified 77 independent loci showing suggestive associations with P values lower than  $9.99 \times 10^{-5}$ . It is these independent loci that we have followed up in this study by

**Fig 2. Pathway enrichment analysis of the *Candida*-induced transcripts at 4 hours.** S3 Table displays all the signalling and biological processes as well as their enrichment p-values.

<https://doi.org/10.1371/journal.pone.0180824.g002>

validating them against 146 disease-matched controls to exclude confounding effects of the patient's clinical background. Following screening of the disease-matched controls, associations at 18 independent loci could be successfully validated ( $P < 0.05$ ; S2 Fig and Table 1).

### eQTL and differential expression prioritize candidaemia causal genes enriched for inflammation and hemostasis

To identify causal genes from these 18 susceptibility loci, three different approaches were applied. In our first approach, we tested whether the 18 candidaemia SNPs were in linkage disequilibrium

**Fig 3. Pathway enrichment analysis of the *Candida*-induced transcripts at 24 hours reveals a stronger effect for hemostasis at 24 hours than 4 hours.** S4 Table displays all the signalling and biological processes as well as their enrichment p-values.

(LD) with variants that alter the protein-coding sequence of the gene (both synonymous and non-synonymous). Two candidaemia-associated SNPs were identified, rs1802141 and rs12491812, that were in strong LD with synonymous variants (S5 Table) and therefore may point to putative causal genes. SNP rs1802141 on chromosome 16 is in strong LD ( $R^2 = 0.82$ ,  $D' = 1$ ) with a synonymous variant, rs61747536, in the *SPNS1* gene (Fig 4A). The *SPNS1* gene, also known as *HSpin1*, has been described to induce a caspase-independent autophagic cell death in cultured

human cells [19]. SNP rs12491812 on chromosome 3 is in strong LD ( $R^2 = 0.89$ ,  $D' = 1$ ) with two synonymous variants, rs2239753 and rs2239752, in the *CISH* gene (Fig 4B). The *CISH* locus has been associated with major infectious diseases such as bacteraemia, tuberculosis, malaria [20], and viral infections such as hepatitis B [21,22], suggesting shared susceptibility genes among different infections.

We should mention that the majority of candidaemia-associated SNPs and proxies fall within intergenic/intronic regions, suggesting that they could have a functional potential by affecting gene expression (S5 Table). Therefore, in our second approach, the 18 candidaemia-associated SNPs were mapped for *cis*-eQTLs using publicly available eQTL datasets from healthy blood donor samples [23–26]. *Cis*-eQTL mapping pinpointed 8 potential causal genes at 6 loci (Table 1).

In our third approach, genes that were located within a 500 kb window around the 18 candidaemia-associated SNPs were extracted and tested as to whether they are differentially expressed after *Candida* stimulation for 4 and 24 hours (S6 and S7 Tables). Within these 'susceptibility regions', we found 18 and 28 genes that are significantly induced upon *Candida*-stimulation for 4 and 24 hours respectively in human PBMCs, raising the possibility that some of these genes could be regulated by the candidaemia-associated SNPs in the context of *Candida* infection. For example, one of the 18 candidaemia-associated SNPs, rs7149309, is located within a locus on chromosome 14 that harbours a cluster of ten serine protease inhibitor genes of the serpin family (Fig 4C). Serpin Family A Member 1 (*SERPINA1*) was significantly expressed in PBMCs in response to *Candida* stimulation for 24 hours compared to the other *SERPIN* genes in the same locus (Fig 4D). *SERPINA1* encodes human alpha-1 antitrypsin (hAAT). A protective role of AAT has been demonstrated against different types of infectious pathogens, such as in bacterial peritonitis [27] and pulmonary *Pseudomonas aeruginosa* infection in cystic fibrosis patients [28].

Together, our three approaches prioritized 31 putative candidate genes for candidaemia susceptibility located in 18 loci (Table 1). Intriguingly, nine out of these 31 prioritized genes (*LAT*, *CD19*, *F5*, *PROC*, *C5*, *SERPINA1*, *SELP*, *SELL* and *SELE*) are enriched in the processes of complement and blood coagulation (Table 1, S3 Fig and S8 Table). As expected, pathway enrichment analysis for all 31 candidaemia genes showed enrichment for cytokine- and immune-related signalling pathways, which is in agreement with our pathway enrichment analysis of the *Candida*-induced transcripts at 4 and 24 hours (Figs 2 and 3, S3 and S4 Tables). In three out of 18 loci, genes that are located in close proximity to the top SNP were shown (Table 1), as we did not find any evidence from the above three approaches to prioritize causal genes.

### **MAP3K8 modulates cytokine production in patients and in experimental models**

One of the candidaemia-associated SNPs, rs1360119, was mapped to the Mitogen-Activated Protein Kinase Kinase 8 (*MAP3K8*) locus (Fig 5A). In particular, rs1360119 is an intronic variant, suggesting that it may affect gene expression. However, rs1360119 does not show *cis*-eQTL effect using publicly available eQTL datasets from healthy blood donor samples (Table 1). That does not exclude the fact that this SNP may show an eQTL effect under context-specific conditions, for instance, upon *Candida* stimulation. In addition, an intronic variant can have functional effects on splicing and, therefore, we can speculate that this SNP may affect splicing.

Of note, MAP kinases are notably attractive therapeutic targets [29]. Therefore, considering the regulatory role of MAP3K8 protein in the production of cytokines in response to lipopolysaccharide [30], bacterial [31,32], and viral pathogens [33], we tested whether the rs1360119 SNP

**Fig 4. Prioritization of candidaemia genes enriched for blood coagulation based on eQTL and differential expression data.** Regional association plots are shown around candidaemia-associated SNPs identified in the Discovery cohort. (A) rs1802141 ( $P = 9.325 \times 10^{-7}$ ) on chromosome 16 is in strong LD with the synonymous variant rs61747536 ( $R^2 = 0.82$ ,  $D' = 1$ ) in the *SPNS1* gene and (B) rs12491812 ( $P = 1.67 \times 10^{-5}$ ) on chromosome 3 is in strong LD ( $R^2 = 0.89$ ,  $D' = 1$ ) with two synonymous variants, rs2239753 and rs2239752, in the *CISH* gene. SNPs are plotted as the  $-\log_{10}$  of the p-value. Local LD structure is reflected by the plotted estimated recombination rates (from HapMap) in the region around the associated SNP (purple diamond) and its correlated proxies. The correlation of the lead SNP to other SNPs at the locus is indicated by colour. (C) Regional association plot for rs7149309, which is located in a locus on chromosome 14, that harbors a cluster of serine protease inhibitor genes of the serpin family, with *SERPINA1* being the most likely causal gene at this locus based on our expression data upon *Candida* stimulation. (D) Log2 fold change expression levels of all *SERPIN* genes upon *Candida* stimulation for 24 hours at a locus on chromosome 14 marked by the candidaemia-associated SNP rs7149309. *SERPINA1* showed a log2 fold change of  $\sim 2.6$ .

<https://doi.org/10.1371/journal.pone.0180824.g004>

correlates with levels of pro-inflammatory cytokines in serum of candidaemia patients. The T allele of the SNP rs1360119 is associated with decreased IL-6 ( $P = 0.018$ ), IL-8 ( $P = 0.024$ ), and interferon (IFN $\gamma$ ) ( $P = 0.013$ ) cytokine levels (Figs 5B–5D). Five other candidaemia-associated SNPs showed a moderate association ( $P < 0.05$ ) with circulating cytokine levels (S9 Table), suggesting that some of the candidaemia-associated variants could determine susceptibility to candidaemia by influencing cytokine production capacity.

To test whether *MAP3K8* is involved in regulating *Candida*-induced cytokine production, we measured cytokine levels upon stimulation of PBMCs with *C. albicans* in the presence or absence of a MAP3K8 chemical inhibitor. Three different cytokines (TNF $\alpha$ , IL-6,

**Fig 5. Candidaemia-associated SNP rs1360119 affects the cytokine expression in serum from patients.** (A) Regional association plot for candidaemia-associated SNP rs1360119, which was mapped to *MAP3K8* locus on chromosome 10. (B) Genotypes of candidaemia-associated SNP rs1360119 are consistently associated with expression levels of (B) IL6 ( $P = 0.018$ ), (C) IL8 ( $P = 0.024$ ) and (D) IFN $\gamma$  ( $P = 0.013$ ) as measured in serum of candidaemia patients. The numbers of individuals per genotype are shown in parentheses. Cytokine levels were log transformed and  $P$  values were obtained using Kruskal Wallis test, and 0.05 was considered statistically significant (minor allele frequency of A = 2% in Europeans from 1000 Genomes Project Phase 3, <http://www.internationalgenome.org>).

<https://doi.org/10.1371/journal.pone.0180824.g005>

and IFN $\gamma$ ) known to be involved in host defence against *C. albicans* were measured [15]. MAP3K8 activity was blocked using three different concentrations of the MAP3K8 inhibitor (10  $\mu$ M, 50  $\mu$ M, and 200  $\mu$ M). Overall, we observed a dose-dependent reduction in all three cytokine levels upon increasing concentration of MAP3K8 inhibitor. A significant decrease in *Candida*-induced TNF $\alpha$  production was observed compared to the DMSO-control at 200  $\mu$ M of MAP3K8 inhibitor ( $P = 0.03$ ) upon 24-hour stimulation (Fig 6A). In addition, a significant decrease in IL-6 was observed upon stimulation with *Candida* conidia for 24 hours with 200  $\mu$ M MAP3K8 inhibitor compared to DMSO ( $P = 0.04$ ) (Fig 6B). We should note that IFN $\gamma$ , one of the most crucial cytokines for efficient host defence for systemic candidiasis, decreased compared to DMSO after stimulation with *Candida* conidia ( $P = 0.057$ ) for 48 hours at 200  $\mu$ M of MAP3K8 inhibitor (Fig 6C). Overall, these experiments demonstrate that MAP3K8 regulates cytokine levels upon *Candida* infection.

**Fig 6. MAP3K8 modulates cytokine production in PBMCs.** Median expression levels of (A) TNFα (B) IL6 and (C) IFNγ in *Candida*-stimulated PBMCs upon inhibition of MAP3K8 at three different concentrations (10 μM, 50 μM, and 200 μM). *Candida conidia* was added at a concentration of  $1 \times 10^5$ /ml. *P* values were obtained using Wilcoxon rank test (\**P* < 0.05). Data shown are from two independent experiments of PBMC stimulation for 24 and 48 hours with conidia of *C. albicans*.

## Discussion

Although *Candida spp* are the fourth most common cause of sepsis in the US, and the most common cause of fungal sepsis in Europe, the difficulty of recruiting sufficient numbers of patients has prevented the use of large GWAS studies to reveal the genetic factors involved in the pathophysiology of *Candida* infections. Our study demonstrates the potential of using a systems genomics approach to obtain novel insights into the genetic basis and host defence mechanisms involved in relatively rare infections in which classical GWAS studies are not applicable. By integrating transcriptomic, genetic and immunological studies, we have identified novel susceptibility genes for candidaemia and new potential therapeutic targets.

The first major group of pathways that are induced during stimulation of human PBMCs with *C. albicans* are genes important for inflammation and innate immunity, cytokine and chemokine synthesis, interferon and inflammasome signalling. This is not surprising as these pathways have been previously shown to have a crucial role for antifungal host defence [15]. The importance of inflammation and innate immunity was also validated by genetic studies

that confirmed that the genes determining susceptibility to candidaemia were enriched for inflammatory genes. However, our analysis has also provided new insight in additional processes that apparently have an important impact on candidaemia. One of these processes is complement activation, which has been shown to modulate cytokine production induced by *Candida* stimulation [34].

Hemostasis is another important biological process suggested by our study to be involved in susceptibility to candidaemia. Hemostasis is known to be strongly activated during sepsis and to interact with the inflammatory responses [35–38]. Strong interactions between immune defence and hemostasis are well documented for bacterial infections, and hemostasis has been previously associated with an increased susceptibility for bacterial sepsis [37,39,40]. Some of the hemostasis genes that we identified as candidaemia susceptibility genes (*SERPINA1*, *LAT* and *F5*) have also been shown to be important for bacterial sepsis (S4A Fig) [41]. Future studies should examine the involvement of these pathways and mechanisms in systemic *Candida* infection, especially as platelets contain several anti-fungal defensins [42], indicating their potential involvement in candidaemia. For example, an examination of protein-protein interaction data using the Plateletweb database found that 14 of our candidaemia susceptibility proteins were found in platelets (S4B Fig).

Another novel observation of the present study is the association of *SERPINA1* gene with susceptibility to candidaemia. Mutations in this gene lead to AAT deficiency and predispose individuals to chronic obstructive pulmonary disease and liver diseases [43,44]. Considering the important role of AAT in modulation of inflammation, as well as the recent beneficial effect of human AAT against bacterial infections [45], hAAT could represent a potential novel adjuvant immunotherapy against systemic *Candida* infection.

*MAP3K8* is known as a critical gene in innate immune responses linking pattern recognition receptors such as Toll-like receptors (TLRs) to TNF production through activation of extracellular signal-regulated kinase [30,46]. In this study we also demonstrate that *MAP3K8* plays an important role in *Candida* infection by modulating cytokine production. The link of *MAP3K8* with TLR-signalling suggests that the innate immune response is important in the context of *Candida* infection. In particular, non-synonymous SNPs in TLR1 have previously been associated with increased susceptibility to candidaemia, highlighting the role of TLRs in the recognition of *Candida* species [47]. Furthermore, the critical role of *MAP3K8* in host immune defence has been demonstrated for other infectious pathogens including influenza virus [33] and *Listeria monocytogenes* [32]. Most importantly, *MAP3K8* is an important and novel therapeutic target for inflammatory diseases [48]. A recent computational approach using publicly available transcriptome datasets for the discovery of common immunomodulators in fungal infections also pinpointed *MAP3K8* and *SERPINE1* in the top ten consistently perturbed gene sets [49]. However, further functional studies are needed to shed light on the role of these genes in host defence against *Candida* infection and to understand their potential as therapeutic targets.

Several limitations also apply to this study. First, the patient cohort study is relatively small, which limited our power to identify many of the genetic factors influencing susceptibility to candidaemia. Second, we lack genetic validation in an independent cohort of patients. This is because no such cohort is currently available: the cohort studied here is the largest candidaemia cohort currently available. In addition, a potential limitation of the present study is that the Immunochip platform covers only 5% of the human genome, i.e. we still lack genome-wide information. This means that further critical genetic variations for candidaemia remain to be discovered on a genome-wide scale. Furthermore, it should be mentioned that *C. albicans* is a polymorphic fungus and is encountered either as yeast or hyphal forms. The transition between conidia and hyphae is a virulence trait of *C. albicans* and mutants that are locked in

the yeast form are less virulent in experimental models of disseminated candidiasis [50,51]. Differential cytokine expression and excretion by immune cells may explain the increased invasiveness of hyphae. For instance, hyphae form has been shown to be unable to induce IFN $\gamma$  in either human PBMCs or murine splenic lymphocytes and conidia induced a much higher TNF $\alpha$  production than hyphae did [52]. This differential cytokine expression may be attributed to structural differences in the cell wall between yeast and hyphal forms and therefore, the human innate immune system can discriminate between yeast and hyphae [53]. In addition, the accessibility of different pathogen associated molecular patterns (PAMPs) between hyphae and conidia of *C. albicans* as well as the potential of only hyphae to activate the inflammasome can explain the induction of immune responses that discriminate between conidia and hyphae forms [53,54]. Thus, by using only heat-killed *C. albicans* conidia in the present study may not represent the full physiological conditions in humans, and further studies should address the differential effect of both forms in PBMCs. Last, *C. albicans* strains may vary in pathogenicity and, therefore, may elicit different host immune responses making it interesting to consider more clinical strains (in addition to UC 820) for validation in the future.

To conclude, the application of an unbiased, hypothesis-free, systems integrative genomics approach has the power to identify novel susceptibility genes for infectious diseases such as systemic candidiasis. In this study, this approach highlighted genes in inflammation, innate immunity and hemostasis pathways that contribute to the genetic susceptibility against candidaemia. We therefore believe that such integrative approaches are an important tool for future identification of genetic susceptibility to rare infectious diseases.

## Supporting information

**S1 Fig.** Heatmaps showing the expression of protein-coding genes, which showed >1.5-fold higher expression, upon (A) 4 and (B) 24-hour stimulation with *C. albicans* in PBMCs from healthy volunteers. RPMI medium was used as control. (adjusted  $P < 0.05$ ). (TIF)

**S2 Fig. Immunochip-wide association analysis with candidaemia.** Manhattan plot highlighting the 18 independent loci showing suggestive association with candidaemia ( $P < 9.99 \times 10^{-5}$ ) using a second set of case-matched controls. The y-axis represents the  $-\log_{10}P$  values of 122,779 SNPs. Their chromosomal positions are shown on the x axis. The dotted line represents the suggestive threshold for association ( $P < 9.99 \times 10^{-5}$ ). P values were not corrected for multiple testing when testing for association with candidaemia susceptibility at 18 independent loci identified in the discovery stage. (TIF)

**S3 Fig. Pathway enrichment analysis based on KEGG and Reactome sources of all 31 candidaemia genes prioritized based on eQTL, differential expression upon *Candida* stimulation and proximity to top SNP.** Candidaemia genes showed an expected enrichment for cytokine signalling pathways and showed a strong enrichment for complement and coagulation pathways. Each node represents a separate pathway whose number of genes and P-value are encoded as node size and node colour, respectively. Two nodes are connected by an edge if they share members. The edge width reflects the relative overlap (corresponding to the Fowlkes-Mallows index) between the nodes, while the edge colour encodes the number of shared gene members. (see.tif image) (TIF)

**S4 Fig.** (A) Heatmap depicts the false discovery rate (FDR) of differentially expressed genes in sepsis as identified by Davenport *Et al* in their discovery and validation cohort. These genes

were differentially expressed in response to *Candida* stimulation as well. (B) Proteins encoded by 14 candidaemia susceptibility genes detected in platelets using plateletWeb (<http://plateletweb.bioapps.biozentrum.uni-wuerzburg.de/plateletweb.php>). (see.tif image) (TIF)

Interleukin receptor SHC signaling	195	19 (9.8%)	0.00958	0.0679	Reactome	2.02

**Table S5.** Candidaemia-associated SNPs and variants with  $r^2 \geq 0.8$ . SNPs rs12491812 and rs1802141 were in strong linkage disequilibrium (LD) with synonymous variants located in *CISH* and *SNPS1* genes respectively (source: Haploreg <http://archive.broadinstitute.org/mammals/haploreg/haploreg.php>).

#### Abstract

Cytokines play a critical role in anti-fungal host defence, but a comprehensive approach to understanding the genetic architecture of cytokine responses against fungi and their role in fungal disease susceptibility is still lacking. To address this knowledge gap, we assessed the cytokine production capacity in different cellular systems following stimulation with three different opportunistic fungal pathogens: *Candida albicans* (yeast and hyphae), *Aspergillus fumigatus* and *Cryptococcus neoformans*. The inter-indi-

vidual variation pattern in cytokine production was specific for each fungal stimulus, and was similar between *C. albicans* yeast and hyphae. Using genome-wide genetic analysis we identified a novel significant locus that regulates IL-17A production upon stimulation with *C. albicans* hyphae. To explain susceptibility to systemic fungal infections, we performed the first candidaemia genome-wide association study (GWAS) and identified genes at 21 independent cytokine QTLs important for disease susceptibility. These loci were enriched for the lipid metabolism functional pathway. Our data suggest that genetic loci that affect cytokine responses to stimulation with fungi can partly explain an individual's fungal disease susceptibility.

Keywords: *C. albicans*, *A. fumigatus*, *C. neoformans*, cytokine-QTLs, susceptibility, candidaemia, genetic variants, lipid metabolism

## Introduction

Invasive fungal infections are an increasingly significant cause of sepsis in critically ill and immunocompromised patients and are associated with high morbidity and mortality. The majority of fungal-related deaths are caused by two fungal species acquired by the environment, namely, *Cryptococcus* and *Aspergillus* species, and by opportunistic *Candida* species, which are mainly part of the normal gut flora<sup>1</sup>. *Candida albicans* (*C. albicans*) is the most predominant fungal pathogen that causes both invasive and mucosal fungal infections. It is a dimorphic fungus as it grows both as yeast and filamentous cells, and causes approximately 250,000 new systemic infections on a yearly basis, leading to more than 50,000 deaths<sup>2,3</sup>. While *Candida* spp. co-exists as commensal in the human gastrointestinal tract and other mucous membranes, *Candida* can invade tissues and eventually blood circulation when epithelial barrier function is impaired and/or the host immune system is compromised, leading to systemic infections. From the bloodstream, *Candida* can disseminate to vital organs, eventually leading to organ failure followed by death.

Both innate and adaptive immune mechanisms are crucial for an effective host defence against fungi. The innate immune system represents the first line defence by recognition of the pathogen, followed by phagocytosis and/or killing. One of the defence mechanisms used by phagocytes is the use of reactive oxygen species (ROS) against various pathogens, including fungi<sup>4</sup>. Subsequently, innate immune cells contribute to the activation of adaptive immune response through antigen presentation and secretion of pro-inflammatory cytokines<sup>5,6</sup>. Cytokines in par-

ticular play a critical role during anti-*Candida* host immune defence, and recombinant cytokines have been proposed as adjunctive therapy in systemic *Candida* infection<sup>7,8</sup>. Administration of recombinant interferon (IFN)- $\gamma$  also improved immune responses in patients with severe fungal infections<sup>9,10</sup>.

In previous studies from the Human Functional Genomics Project (HFGP) consortium, we assessed the impact of genetic polymorphisms on cytokine production capacity in response to several pathogens, including fungi, in 500 healthy volunteers<sup>11</sup>. However, it remains unknown to what extent genetic variants that determine cytokine variability in response to *C. albicans*, can also affect susceptibility to systemic fungal infections, namely, candidaemia. In the present study, we first explored the genetic architecture of cytokine responses induced by the opportunistic fungal pathogen *C. albicans* and by the two other common fungal pathogens acquired by the environment *A. fumigatus* and *C. neoformans*. We also explored the differences in the cytokine responses induced by the two morphotypes of *C. albicans* (yeast and hyphae). In addition, we investigated the hypothesis whether susceptibility to candidaemia is explained by modulating the levels of pro-inflammatory cytokines. For this, we performed the first genome-wide association study (GWAS) of candidaemia on the largest candidaemia cohort published to date. Here we identified independent loci associated with candidaemia susceptibility to influence different cytokines produced from three different cell systems in response to *C. albicans* (Fig. 1). Finally, we tested whether these loci influence ROS production and *Candida* killing. Identifying genetic loci that influence susceptibility to systemic *Candida* infections by modulating cytokine levels will help us understand what drives susceptibility, a crucial step for the design of novel preventive and therapeutic strategies.

## Results

### Variations in cytokine immune response to opportunistic fungal pathogens in humans

To study the variations in cytokine responses to the three opportunistic fungal pathogens, we stimulated immune cells in three different cellular systems, whole blood (WB) for 48 hours, peripheral blood mononuclear cells (PBMCs) for 24 hours or 7 days and monocyte-derived macrophages for 24 hours with *C. albicans*, *A. fumigatus* and *C. neoformans* (Fig. 1)<sup>11</sup>. We used PBMCs, which is a mixed population of several cell types to capture interactions between different immune cell types. To study the interaction of different immune factors, such as between immune cell populations (granulocytes, monocytes and lymphocytes) and complement, antibodies and other serum factors, we also used WB stimulations. In addition to PBMCs and WB, we used monocyte-derived macrophages as these

**Fig. 1.** Study overview. We collected blood samples from 500 healthy individuals in the 500FG cohort, isolated their DNA and genotyped it using the HumanOmniExpressExome-8 v1.0 SNP Chip. Imputation increased the genotype information to approximately 8 million SNPs. Whole blood or PBMCs or monocyte-derived macrophages were also used to perform a series of stimulation experiments with three different fungal species (*C. albicans*, *A. fumigatus* and *C. neoformans*) to profile the cytokines released in the three cell systems. Using the genotype information and cytokine measurements, we mapped fungal-response cQTLs. To identify whether cQTLs influence susceptibility to candidaemia, we performed a GWAS to test the association of genetic variants to disease susceptibility by using the largest candidaemia cohort available to date (178 cases and 175 case-matched controls).

cells are key effector cells in antifungal defence<sup>5</sup>.

Unsupervised clustering of the levels of monocyte-derived cytokines (IL-1 $\beta$ , IL-6 and TNF $\alpha$ ) and T-cell-derived cytokines (IFN $\gamma$ , IL-17A and IL-22) upon stimulation with *C. albicans* yeast and hyphae in WB, PBMCs and monocyte-derived macrophages indicated that there is a clear distinction between WB, PBMCs and macrophage-derived cytokines (Fig. 2A). This observation suggests that additional variation in cytokine responses in WB may be explained by the contribution of different immune factors, such as different immune cell types (e.g neutrophils) or plasma factors, compared to the other two cell systems (PBMCs or monocyte-derived macrophages). In addition, clustering revealed a separation between mono-

**Fig. 2.** Cytokine responses are organized to respond specifically toward fungal pathogens. Results from unsupervised hierarchical clustering (A) of cytokine responses in macrophages, PBMCs and WB induced by *C. albicans* yeast and hyphae and (B) of the cytokine responses induced by *C. albicans*, *A. fumigatus* and *C. neoformans* in PBMCs. Clustering was performed using Spearman's correlation as the measure of similarity. Red indicates strong positive correlation. Blue indicates strong negative correlation. In (A), cluster 1 depicts the positive correlation of IL-6 and TNF $\alpha$  derived by macrophages upon stimulation with *C. albicans* yeast. Clusters 2 and 4 show that there is a clear distinction between the monocyte-derived cytokines (IL-6, TNF $\alpha$  and IL-1 $\beta$ ) and the T-cell-derived cytokines (IL-17A, IFN $\gamma$  and IL-22) upon stimulation with *C. albicans* yeast and hyphae. Cluster 3 depicts the positive correlation of monocyte-derived cytokines and the T-cell-derived cytokine IFN $\gamma$  upon stimulation with *C. albicans* yeast in WB. In (B), cluster 1 depicts the positive correlation between monocyte-induced cytokines on stimulation of PBMCs with *C. albicans* yeast and hyphae and with *A. fumigatus* (IL-6 and TNF $\alpha$ ). Cluster 2 depicts the positive correlation between monocyte- and T-cell-derived cytokines on stimulation of PBMCs with *C. neoformans*. Cluster 3 depicts the positive correlation among cytokines derived from T-helper cells on stimulation of PBMCs with both *C. albicans* yeast and hyphae and with *A. fumigatus* (IL-22, IL-17A and IFN $\gamma$ ). macroPG: macrophages, PBMC: Peripheral blood mononuclear cells, WB: whole blood.

cyte-derived and T-cell-derived cytokine responses within the PBMC fraction. Furthermore, the production of cytokines induced by the two morphotypes of *C. albicans* (yeast and hyphae) was generally strongly correlated.

To assess the correlation between cytokine responses induced by *C. albicans*, *A. fumigatus* and *C. neoformans*, we performed unsupervised clustering of cytokines produced in PBMCs in response to all three fungi. Clustering was mainly dependent on specific fungal species rather than between different cytokines, and we observed distinct clusters for *C. albicans*, *A. fumigatus* and *C. neoformans* (Fig. 2B). At the level of host anti-fungal response, this observation further substantiates the concept that immune responses are organized to respond specifically to defined fungal pathogens rather than to respond uniformly to any infection with the production of the same cytokines<sup>11</sup>. Interestingly, we observed a stronger positive correlation between cytokines induced by *A. fumigatus* and *C. albicans* compared to those induced by *C. neoformans* (Fig. 2B). In contrast, only the T-cell-derived cytokines induced by *C. neoformans* were more similar to the T-cell-derived cytokine responses induced by *C. albicans* yeast (Fig. 2B). Of note, the distinct cluster between monocyte-derived and T-cell-derived cytokines was weaker for *C. neoformans*-induced cytokine responses compared to the *C. albicans*-induced responses (Fig. 2B).

### Genetic variation has a role in heterogeneity of anti-*Candida* cytokine responses

We observed that cytokine levels show a significant variation upon stimulation with *C. albicans* yeast and hyphae in all our stimulation cell systems compared to stimulation with the medium control (Figure S1). We have previously shown that non-genetic host factors such as age and gender affect cytokine responses to fungal stimulation<sup>12</sup>, while cell counts had only a minor effect<sup>13</sup>. Additionally, we identified three genome-wide significant SNPs that affect *C. albicans*-yeast-induced cytokines (cytokine-QTLs or cQTLs) and two genome-wide significant SNPs that affect *C. neoformans*-induced cytokines, indicating that genetics have an impact on cytokine responses upon fungal stimulation<sup>13</sup>.

Given that clustering analysis revealed a strong positive correlation between cytokine responses induced by *C. albicans* yeast and hyphae (Fig. 2), we hypothesized that the cytokine responses to each of these morphotypes are regulated by similar genetic factors. To test this hypothesis, we investigated whether the same genetic variants determine the cytokine responses induced by the two morphotypes of *C. albicans*. For this, we first mapped *C. albicans*-hyphae-response cQTLs by correcting for age, gender and cell counts using genome-wide genotypes from the 500FG cohort. A novel genome-wide significant cQTL ( $P < 5 \times 10^{-8}$ ) at chromosome 16p12.2 (Fig. 3A) was identified. This top cQTL, rs13333993 was associ-

**Fig. 3.** Genome-wide QTL mapping identifies a novel *C. albicans* hyphae response cQTL. (A) Manhattan plot showing the genome-wide QTL mapping results for *C. albicans* hyphae-induced IL-17A levels. Y-axis represents the  $-\log_{10}P$  values of cQTLs. Their chromosomal positions are shown on the X-axis. Horizontal dashed line represents the genome-wide significance threshold for association ( $P < 5 \times 10^{-8}$ ). (B) Box plot showing the association of the genotypes of SNP rs13333993 with IL-17A levels upon stimulation with *C. albicans* hyphae in PBMCs for 7 days. The number of individuals per genotype is shown in parentheses below the box plot. (C) Regional association plot showing the  $-\log_{10}P$  for SNPs centered on the most strongly associated signal (rs13333993, purple diamond) associated with IL-17A levels upon *C. albicans* hyphae stimulation in PBMCs for 7 days.

ated with IL-17A levels induced by *C. albicans* hyphae (Fig. 3B), and this SNP is located in close proximity to the *HS3ST2* gene that codes for the heparan sulfate glucosamine 3-O-sulfotransferase 2 protein (Fig. 3C). Further investigation revealed that this SNP does not influence the gene expression of *HS3ST2*, as shown in publicly available eQTL datasets<sup>14,15</sup>.

Given that unsupervised clustering of the cytokine responses induced by *C. neoformans* and *C. albicans* yeast indicated a positive correlation within the T-cell-derived cytokines induced by these two fungi (Fig. 2B), we investigated whether this correlation is driven by shared genetic components. For this, we test-

ed if independent *C. albicans*-response cQTLs ( $P < 9.99 \times 10^{-4}$ ) could be associated with cytokine levels induced by *C. neoformans* with a nominal significance ( $P < 0.05$ ). We found a significant enrichment of shared cQTLs from T-cell-derived cytokines induced by *C. albicans* yeast and by *C. neoformans* compared to monocyte-derived cytokines (Figure S2). Of note, this enrichment remained significant across the different P-value thresholds used to define cQTLs (Figure S2).

**Fig. 4.** *PLA2G4B* locus is associated with candidaemia susceptibility. (A) Manhattan plot of SNPs associated with candidaemia susceptibility identified by GWAS. GWAS revealed a locus strongly associated with susceptibility to candidaemia at chromosome 15 ( $P = 7.97 \times 10^{-8}$ , OR = 0.4002). Y-axis represents  $-\log_{10}P$  values of SNPs. X-axis shows chromosomal positions. Blue line is the suggestive threshold for association ( $P < 9.99 \times 10^{-5}$ ). (B) Regional association plot for the candidaemia-associated SNP, rs8028958 (purple diamond), which mapped to the *JMJD7-PLAS2G4B* locus at chromosome 15. Each dot represents a SNP, and the linkage disequilibrium of neighboring SNPs with the top SNP is color-coded. Y-axis represents  $-\log_{10}P$  values of SNPs. X-axis shows chromosomal positions.

## Candidaemia GWAS identifies the *PLA2G4B* locus association with susceptibility

To identify genetic variants associated with susceptibility to candidaemia, we genotyped 178 well described candidaemia patients<sup>65</sup> and 175 case-matched controls of European ancestry on a genome-wide scale and imputed the genotype data using the Human Reference Consortium (HRC). After quality control filtering per SNP and sample, we obtained 161 patients and 152 case-matched controls for whom we had genotype information on 5,326,313 SNPs variants, which were tested for disease association. Finally, this GWAS identified 235 SNPs in 70 independent loci that show suggestive disease associations ( $P < 9.99 \times 10^{-5}$ ). Among these loci, a SNP on chromosome 15, rs8028958, showed the strongest association with susceptibility to candidaemia ( $P = 7.97 \times 10^{-8}$ , OR = 0.4002) (Fig. 4A). This top

associated SNP is located within the intronic region of the *SPTBN5* gene (Fig. 4B). Previous eQTL analysis showed that SNP rs11070352, a proxy SNP to rs8028958 ( $r^2 = 0.9$  and  $D' = 0.99$ ), affects the expression of *EHD4* ( $P = 7.76 \times 10^{-27}$ ) and *JMJD7-PLA2G4B* ( $P = 2.63 \times 10^{-18}$ ) in WB<sup>15</sup>. In addition, eQTL data from GTEx project also indicated the effect of this SNP on different genes in different tissues including *PLA2G4B*, suggesting its strong regulatory function<sup>16</sup>. *JMJD7-PLA2G4B* encodes a fusion protein known as JMJD7-PLA2G4B and is a paralog gene of *PLA2G4B*<sup>17</sup>. In addition, we observed that differential expression analysis upon *C. albicans* stimulation in PBMCs prioritized *PLA2G4B* as a plausible candidaemia susceptibility gene (Figure S3A). *PLA2G4B* gene expression was significantly decreased ( $P = 1.02 \times 10^{-13}$ ) upon stimulation of PBMCs with *C. albicans* after 24 hours compared to RPMI stimulated PBMCs.

Given the strong association of rs8028958 with susceptibility to candidaemia ( $P = 7.97 \times 10^{-8}$ ) and the significant differential expression of *PLA2G4B* in response to *C. albicans* in PBMCs ( $P = 1.02 \times 10^{-13}$ ), we performed *in vitro* functional experiments to validate the role of *PLA2G4B* in anti-*Candida* host immune defence. To investigate the importance of the *PLA2G4B* locus in the host immune response against *C. albicans*, human primary monocytes were isolated and specific *PLA2G4B* siRNA or control siRNA were used to silence the gene prior to stimulation with *C. albicans*. In the following experiment, cytokine production capacity of TNF $\alpha$ ,

**Fig. 5.** *C. albicans* killing capacity of primary monocytes upon targeted silencing of the *PLA2G4B* gene. A significant reduction of the killing capacity of monocytes was observed upon siRNA silencing

of the *PLA2G4B* gene compared to control siRNA. Data from three experiments with at least three donors per experiment was pooled. CFU: colony forming units.

IL-1 $\beta$ , IL-6 and IL-1Ra, known to play an important role in anti-*Candida* host immune defence<sup>5</sup>, were measured. Comparing cytokine levels of non-targeting control siRNA with *PLA2G4B* siRNA revealed a decrease in IL-6 and TNF $\alpha$  production in the targeted group (Figure S3B). Finally, targeted silencing of *PLA2G4B* also led to a reduction of the capacity of monocytes to kill *C. albicans* yeast (Fig. 5), suggesting a role for *PLA2G4B* in host defence against *C. albicans*.

### SNPs modulating cytokine levels associate with candidaemia susceptibility

To investigate whether SNPs modulating cytokine levels upon *C. albicans* stimulation are associated with candidaemia susceptibility – which would demonstrate the importance of inherited cytokine production capacity for susceptibility to infection – we tested whether genetic variants associated with susceptibility to candidaemia influence cytokine levels in response to *C. albicans* yeast or hyphae

using the results of the previous cQTL mapping. We found 75 SNPs from 21 independent candidaemia-susceptibility loci (Table 1) that modulate cytokine levels upon *C. albicans* stimulation in any of the cell systems (PBMCs, WB, and macrophages). Twenty SNPs modulate multiple cytokines upon stimulation with both *Candida* morphotypes (Table S1). These observations suggest that susceptibility can be partly explained by defects in cytokine pathways, and that there are also other alternative mechanisms involved in candidaemia susceptibility.

Moreover, from these loci, we extracted genes in a 500 Kb window upstream and downstream of each cQTL and prioritized genes that could determine susceptibility by modulating cytokine levels (Table 1). For gene prioritization, we used publicly available eQTL mapping datasets from blood<sup>14,15</sup>. Our prioritization identified a number of genes, including *ALOX15B*, *GGT5*, *HSD17B4*, *JMJD7-PLA2G4B*, *AGPAT1*, *TTC7B* and *ALOXE3*, known to be involved in different lipid metabo-

**Table 1.** SNPs modulating cytokines in response to *C. albicans* yeast and hyphae ( $P < 0.05$ ) in one of the cell systems (blood, PBMCs and monocyte-derived macrophages) show an association with susceptibility to candidaemia ( $P < 9.99 \times 10^{-5}$ ).

<sup>d</sup> Gene differentially expressed in response to *C. albicans* stimulation in PBMCs at 4 hours

<sup>e</sup> Twenty-one independent *C. albicans* yeast or hyphae-response cQTLs associated with candidaemia susceptibility ( $P < 0.05$ ) in any of the cell systems: WB, PBMCs and monocyte-derived macrophages.

<sup>f</sup> Genes in a 500 Kb window upstream and downstream of each cQTL were prioritized from each locus based on gene expression data of PBMCs in response to *C. albicans* for 4 and 24 hours and eQTL data from whole blood.

lism processes, a finding which was also confirmed by pathway enrichment analysis (Table S2).

Lastly, as ROS production is an important aspect of phagocyte-mediated host responses, we tested whether any of the 21 susceptibility loci that influence cytokine levels has an impact on *Candida* killing through influencing ROS production. For this, we mapped QTLs using genotypes and measurements of ROS production and *Candida* killing of 137 samples from an independent population-based cohort (200FG)<sup>18,19</sup>. We found two loci that have an impact on *Candida* killing by influencing ROS production (Fig. 6A and B). In particular, cQTL (rs2725008), an intronic variant of *CSMD1* gene at chromosome 8 (Fig. 6A), influences *Candida*

**Fig. 6.** Related to Table 1. Two susceptibility loci influencing cytokine levels have an impact on *Candida* killing by influencing ROS production. Regional association plots for (A) rs2725008 and (B) rs9565423 showing the  $-\log_{10}P$  of association for susceptibility of SNPs centered on the most strongly associated signal (purple diamond). Each dot represents a SNP, and different colors of dots indicate varying linkage disequilibrium with the top signal. Box plots showing the association of genotypes between SNP rs2725008 at chromosome 8 with (C) *Candida* killing (in percentage) and (D) ROS production, and between SNP rs9565423 at chromosome 13 with (E) *Candida* killing (in percentage) and (F) ROS production. The data shown were generated using 137 samples from 200FG cohort for whom both genotype and measurements of ROS production and *Candida* killing were available. For normalization,  $\log_2$  transformation was used for the measurements of ROS production and rank-based inversed normal transformation for the percentages of *Candida* killing.

killing ( $P\ 3.88 \times 10^{-2}$ ) through affecting ROS production (RLU/sec) ( $P\ 6.78 \times 10^{-3}$ ) (Fig. 6 C to D). In addition, a second variant rs9565423 at chromosome 13 (Fig. 6B), a proxy ( $r^2 \geq 0.8$ ) to susceptibility variant rs6563046 influencing cytokines, found to influence *Candida* killing ( $P\ 4.07 \times 10^{-2}$ ) and ROS production ( $P\ 5.26 \times 10^{-2}$ ) with a P nominal significance (Fig. 6 E to F).

These findings indicate that these two loci have a functional role in *Candida* killing by influencing ROS production and that cytokines may influence *Candida* killing through other mechanisms, independent of ROS production.

## Discussion

In a given at-risk population not all patients develop infections, which indicates that there is a strong genetic influence on individual susceptibility to different infections<sup>20</sup>. Although systemic fungal infections result in high morbidity and mortality in developed countries, genetic association studies that identify risk genes for systemic fungal infections are extremely challenging because of the difficulty of enrolling large numbers of case-matched controls. To circumvent these challenges, we identified genetic variants that affect human cytokine responses to common opportunistic fungal pathogens (*C. albicans*, *A. funigatus* and *C. neoformans*) by studying the variability of cytokine production in PBMCs isolated from healthy volunteers from 500FG cohort. Further, we explored the genetic variation that determines cytokine responses induced specifically by the two morphotypes of *C. albicans* (yeast and hyphae) in PBMCs. To explore whether genetic variation influencing cytokine levels in response to *C. albicans* explains susceptibility to candidaemia, we intersected the *Candida*-response cQTLs with genetic variants identified by the first GWAS exploring susceptibility to candidaemia using the largest cohort available to date.

Our study reveals that the inter-individual variations in cytokine production were similar for *C. albicans* yeast and hyphae. Through genetic analysis we identified a significant novel genome-wide genetic locus that regulates IL-17A production upon stimulation with *C. albicans* hyphae. We also found a significantly higher contribution of shared genetics in the regulation of T-cell-derived cytokine levels in response to both *C. albicans* and *C. neoformans*, a relationship that was not present in monocyte-derived cytokines. Finally, by integrating *Candida*-response cQTLs with SNPs associated with candidaemia-susceptibility in our GWAS, we identified 21 independent cQTLs important in determining susceptibility to candidaemia.

To cause infection, fungi need to cross skin and/or mucosal barriers, penetrate

and invade underlying tissues and at the same time resist human immune defences<sup>21</sup>. To achieve this, these fungi adapt to changing environments by developing different escape strategies. The human host responds to these strategies by organizing the host cytokine response in a pathogen-specific manner, shown by the distinct clusters of correlation we observed for the cytokine production induced by *A. fumigatus*, *C. albicans* or *C. neoformans* (Fig. 2). It has been shown that *C. albicans* hyphae (associated with tissue invasion) has a different cell wall composition compared to yeast cells (associated with colonization), indicating differential host recognition of hyphae and yeast as well as explaining differences in the virulence of these two morphological forms<sup>22,23</sup>. Interestingly, the high correlation between hyphae- and yeast-induced cytokine responses suggests that cytokine responses to these two morphotypes are regulated by shared genetic and non-genetic factors.

An important finding of the present study is the identification of novel genetic factors that influence *C. albicans*-induced cytokine production while also impacting susceptibility to candidaemia. Moreover, we found a cQTL with genome-wide significance for *C. albicans* hyphae-induced IL-17A production. The gene located closest to this variant is *HS3ST2*, which codes for the heparan sulfate glucosamine 3-O-sulfotransferase 2 protein. *HS3ST2* is an important gene involved in macrophage polarization, and we have previously identified this gene as one of the differentially regulated genes by the TLR locus genotype<sup>24</sup>. These results indicate that some of the cQTLs influencing *Candida*-induced cytokines are downstream of TLR-signaling, which is in line with earlier literature demonstrating the role of TLRs for pattern recognition of *C. albicans*<sup>5</sup>. What remains to be investigated is the precise mechanism through which *HS3ST2* modulates IL-17A production.

One of the most important aspects of our study was our demonstration in an unbiased manner of the strong impact of cQTLs on susceptibility to candidaemia. As shown in Table 1, there are 21 independent cQTLs that modulate susceptibility to candidaemia. Among these polymorphisms, 20 SNPs modulate cytokines in response to both *C. albicans* morphotypes (Table S1). Two loci out of the 21 found to have an impact on *Candida* killing by influencing ROS production, which is one of the major defence mechanism against different pathogens, including fungi<sup>18,19,25</sup>. Of particular interest, rs2725008 is an intronic variant in *CSMD1* gene, which encodes a novel complement-regulatory protein highly expressed in epithelial tissues and in the central nervous system<sup>26</sup>, suggesting that the complement system may have a role in determining susceptibility to *Candida* infections. Notably, the complement system is a major component of the innate immune system and plays a critical role in defending against invading pathogens<sup>27</sup>. Moreover, genes from susceptibility loci that influence cytokines found to be enriched for those involved in lipid and lipoprotein metabolism processes (Table S2). Many metabolic changes including lipid synthesis are shown to be important in regu-

lating cytokine secretion to coordinate immune response<sup>28–30</sup>. In mouse studies, hyperlipoproteinemia increased the susceptibility to systemic candidiasis due to an increased fungal outgrowth in their organs<sup>31</sup>, while a beneficial effect was seen in rats infected with gram-negative bacteria<sup>32</sup>. These data were in agreement with human studies where infusion of lipoproteins enhances the growth of *C. albicans* in the plasma of volunteers<sup>33</sup>. Although the lipid profiles differ between humans and mice, both studies suggest that hyperlipidemia have deleterious effects by enhancing the growth of *C. albicans* in both species. Therefore, it needs to be tested whether the candidaemia-associated SNPs that we have identified in this study influence cytokine levels through affecting lipids and lipoprotein levels. Nevertheless, our data demonstrate the power of a systems-based approach for identifying the most important host defence mechanisms against an infection.

Finally, we have identified a novel genome-wide genetic association of candidaemia with polymorphisms in *PLA2G4B*, a gene encoding the cytosolic phospholipase A2 protein that selectively hydrolyses phospholipids to release lysophospholipids and fatty acids. It has been suggested that PLA2G4B-F enzymes may control phospholipid and/or arachidonate metabolism in a tissue specific manner<sup>34</sup>. However, the role of *PLA2G4B* has never been studied in the context of infectious diseases. Interestingly, specific down-regulation of *PLA2G4B* using siRNA resulted in impairment of the candidacidal properties of monocyte-derived macrophages, confirming its importance in the host response against *C. albicans*.

In conclusion, our study provides an important resource for the understanding of genetic factors in determining cytokine production induced by opportunistic fungal pathogens and susceptibility to candidaemia. The novel strategy we have taken demonstrates the strength of a systems genomics approach to identifying novel risk genes and pathways for fungal infections. In the future, systematic integration of such datasets may also be useful for other infectious diseases and could ultimately lead to the development of novel therapies and treatment strategies that target these genes and pathways.

## Materials and methods

---

### Study populations

*Population-based cohorts.* To understand the variation in cytokine production in humans in response to *C. albicans in vitro*, we used two independent population-based cohorts, 500FG and 200FG, composed of healthy individuals of Western European ancestry from the Human Functional Genomics Project (HFGP, see [www.humanfunctionalgenomics.org](http://www.humanfunctionalgenomics.org)). The 500FG cohort is composed of 534 well-characterized healthy individuals, 237 males and 296 females all between 18

and 75 years old. The 200FG cohort is composed of ~200 healthy individuals from the 'Geldersch Landschap', 'Hoge Veluwe', 'Twickel', and 'Kroondomein het Loo' in the Netherlands, is 77% male and 23% female<sup>13</sup> and has an age range from 23 to 73 years old.

*Candidaemia cohort.* To identify genetic variants associated with candidaemia susceptibility, we performed the first GWAS analysis of a well-described candidaemia cohort with corresponding disease-matched controls<sup>35</sup>. In total, 178 candidaemia cases and 175 disease-matched controls of European ancestry were tested for disease association. The demographic and clinical characteristics of the candidaemia cohort have been described previously<sup>35</sup>. The patients were enrolled between January 2003 and January 2009. Patients must have had at least one positive blood culture for a *Candida* species, with the majority of them infected by *C. albicans*<sup>35</sup>. Case-matched controls were recruited from the same hospital wards as candidaemia cases so that co-morbidities and clinical risk factors for infection were similar. Both candidaemia cases and case-matched controls were enrolled after informed written consent was given at the Duke University Hospital (DUMC, Durham, North Carolina, USA). The study was approved by the institutional review boards at the Duke University Hospital.

### PBMC collection and stimulation experiments

Venous blood from the cubital vein of healthy volunteers was drawn in EDTA tubes after obtaining written informed consent. PBMC isolation was performed as previously described<sup>36</sup>. In short, the PBMC fraction was obtained using density centrifugation in Ficoll-Paque (Pharmacia Biotech). Cells were then washed twice in PBS and re-suspended in RPMI medium supplemented with gentamicin 10 mg/mL, L-glutamine 10 mM and pyruvate 10 mM. PBMCs were counted and re-suspended in a concentration of  $5 \times 10^6$  cells/mL.  $5 \times 10^5$  PBMCs were added in 100  $\mu$ L to round-bottom 96-well plates (Greiner) and incubated with 100  $\mu$ L of stimulus (RPMI, heat killed *Candida albicans* yeast  $1 \times 10^6$ /mL or *Candida albicans* hyphae  $1 \times 10^5$ /mL). After 24 hours or 7 days in the presence of 10% human serum, the supernatants were collected and stored at  $-20^\circ\text{C}$ . Cytokines were measured using different ELISA assays. *C. albicans* yeast cells of the strain ATCC MYA-3573, UC820 were used for the stimulation experiments. To generate hyphae, live yeast forms of *Candida* were grown for 24 hours at  $37^\circ\text{C}$  in RPMI (Gibco-BRL), adjusted to pH 6.4 by using hydrochloric acid. After 24 hours, more than 95% of the yeast cells were grown into hyphae, which were checked by microscope. Hyphae were heat killed for 45 min at  $98^\circ\text{C}$  and resuspended in RPMI to a hyphal inoculum size that originated from  $10^6$ /ml yeast cells (referred to as  $10^6$ /mL hyphae).

### Macrophage differentiation and stimulation

After PBMC isolation, purification of monocytes was performed by hyper-osmotic Percoll density gradient centrifugation.  $1.5 \times 10^5$  cells were seeded in a 96-well flat bottom plate (Greiner). After 24 hours of attachment, 25 nM of either non-targeting siRNA control pool (D-001810-10-05) or *PLA2G4B* (L-187552-01-0005) targeting siRNA (Smartpool, Thermo Scientific) were added for 24 hours. After the transfection period, cells were stimulated for 24 hours with  $1 \times 10^6$ /mL *Candida* yeast. After the stimulation period, supernatants were collected and stored at  $-20^\circ\text{C}$ . Cytokines were measured using different ELISA assays.

### Whole-blood stimulation experiments

100  $\mu\text{L}$  of fresh heparin blood was added to a 48-well plate and then stimulated with 400  $\mu\text{L}$  stimulus (either RPMI or *C. albicans*  $1 \times 10^6$ /mL) for 48 hr at  $37^\circ\text{C}$  and 5%  $\text{CO}_2$ . Supernatants were collected and stored at  $-20^\circ\text{C}$  until used for ELISA.

### Cytokine measurements

Frozen supernatants from PBMCs, monocytes and WB stimulation experiments were measured for IL-1 $\beta$ , IL-6, TNF $\alpha$ , IL-22, IL-17A, and IFN $\gamma$  using commercial available ELISA kits (PeliKine Compact or R&D Systems). All ELISAs were carried out according to manufacturer protocol. Data were analyzed using GraphPad prism v5.0. Data are shown as means  $\pm$  SEM.  $P < 0.05 = *$ ,  $P < 0.01 = **$  and  $P < 0.001 = ***$ .

### ROS production

Induction of reactive oxygen species (ROS) was measured by oxidation of luminol (5-amino-2,3, dihydro-1,4-phthalazinedione).  $5 \times 10^5$  PBMCs of healthy volunteers were resuspended in HBSS and put in dark 96 wells plates. Cells were exposed to  $1 \times 10^6$ /mL *C. albicans* yeast (UC820, heat killed) together with 20  $\mu\text{L}$  of 1mM luminol (final concentration 50  $\mu\text{M}$ ). Chemiluminescence was measured in BioTek Synergy HTreader at  $37^\circ\text{C}$  for 1 hour with intervals of 2.23 minutes. The relative luminescence units per second (RLU/sec) within the area under the curve (AUC) were plotted against time and analysed by using Graphpad Prism v5.0.  $P < 0.05 = *$ ,  $P < 0.01 = **$  and  $P < 0.001 = ***$ .

### Monocyte fungal killing assays

For the monocyte siRNA experiments,  $1.5 \times 10^5$  cells were directly seeded into 96-well flat bottom plates. After 24 hours of siRNA treatment,  $1 \times 10^6$ /mL live *C. albicans* yeast was added for 24h of incubation at  $37^\circ\text{C}$ . Following incubation, well contents were serial diluted in sterile water and plated on Sabouraud agar for counting of colony forming units. Data was stratified regarding genotypes for

SNP rs8028958 in *PLA2G4B*. Data from three experiments with at least three donors per experiment was pooled and data was analyzed using Graphpad Prism v5.0.  $P < 0.05 = *$ ,  $P < 0.01 = **$  and  $P < 0.001 = ***$ .

### **Variance analysis and cytokine clustering**

We first log-transformed raw cytokine levels and filtered out cytokine measurements showing little/no variation across individuals as previously described<sup>24</sup>. We used the Levene's test to check the equality of variance of cytokine levels before and after stimulation. We performed unsupervised hierarchical clustering using Spearman's correlation as the measure of similarity. All statistical analyses regarding the cytokine data were performed in R (<https://www.R-project.org/>).

### **Genotyping, quality control and imputation of the 500FG cohort**

DNA obtained from the 500FG cohort was genotyped using the commercially available Illumina HumanOmniExpressExome-8 v1.0 SNP chip. Genotype calling was performed using Optical 0.7.0 using default settings<sup>37</sup>. We applied quality control per sample to exclude samples with a call rate  $\leq 0.99$  and quality control per SNP to exclude variants with a Hardy-Weinberg equilibrium  $\leq 0.0001$ , a call rate  $\leq 0.99$  and a minor allele frequency (MAF)  $\leq 0.001$ . We identified 17 ethnic outliers by merging multi-dimensional scaling plots of samples with 1000 Genomes data, and these outliers were excluded from further analysis<sup>24</sup>. The quality control filters resulted in a dataset of 483 samples containing genotype information on 518,980 variants for further imputation. The strands and variants-identifiers were aligned to the reference Genome of the Netherlands (GoNL, Genome of the Netherlands Consortium, 2014<sup>38</sup>) dataset using Genotype Harmonizer<sup>39</sup>. The data were phased using SHAPEIT2 v2 using GoNL as a reference panel<sup>40,41</sup>. We selected SNPs that showed an INFO score  $\geq 0.8$  upon imputation for further cytokine QTL mapping.

### **Genotyping, quality control and imputation of the candidaemia cohort**

Isolated DNA obtained from case and control samples was genotyped using the commercially available SNP chips, HumanCoreExome-12 v1.0 and HumanCoreExome-24 v1.0 BeadChip from Illumina (<https://www.illumina.com>). Genotype calling was performed using Optical 0.7.0 using the default settings<sup>37</sup>. Strands of variants were aligned and identified against the 1000 Genome reference panel using Genotype Harmonizer<sup>39</sup>. We then imputed the samples on the Michigan imputation server using the human reference consortium as a reference panel, and we filtered variants with an  $R^2$  of 0.3 for imputation quality<sup>42</sup>. After excluding imputed variants with a MAF  $< 0.10$  and variants within the HLA region, we applied quality control per sample and removed 15 individuals (5 cases and 10 controls) due to excess/reduced heterozygosity and cryptic relatedness. Next,

we applied SNP quality control filters to exclude SNPs with (a) a MAF of  $< 0.05$  and (b) a Hardy-Weinberg equilibrium of  $P < 1 \times 10^{-6}$  in control samples only. We also identified 25 ethnic outliers (12 cases and 13 controls) by multidimensional scaling analysis (performed in PLINK on the  $N \times N$  matrix of genome-wide IBS pairwise distance) of candidaemia patients and disease-matched controls for the two first principle components (Figure S4A). The quantile-quantile plot that shows the distribution of the observed  $-\log_{10}$  for the whole-genome SNPs against the theoretical distribution of expected  $-\log_{10}$  indicated no or little evidence of population stratification (Figure S4B). The genomic inflation factor based on median  $\chi^2$  was equal to 1 ( $\lambda = 1$ ). Quality control filters resulted in a dataset of 161 cases and 152 disease-matched control samples containing genotype information on 5,326,313 SNP variants for further testing for association with candidaemia susceptibility.

### Cytokine QTL mapping

We selected 442 individuals from 500FG for whom both genotype and cytokine data were available. We obtained cell count data measured by FACS for total lymphocytes, T cells, B cells, monocytes and NK-cells from 487 individuals from the 500FG cohort. For cytokine QTL mapping, we used 409 samples with genotype, cytokine and cell-count data. Of these, 17 samples were excluded due to genetic differences. To correct the cytokine distributions for QTL mapping, we used a linear model adjusting for age, gender and cell-count. Raw cytokine levels were first log-transformed and the correlation between cytokine production and genotype was tested by linear regression model with age and gender as co-variables using the R-package Matrix-eQTL. Since the stimulation-cytokine combinations cannot be regarded as completely independent, the total number of independent tests among all phenotypes will be much less than the number of phenotypes measured, and therefore correcting for the number of SNPs tested for each trait should be sufficient. We considered  $P < 5 \times 10^{-8}$  to be the threshold for significant cQTLs. *C. albicans* response QTLs ( $P < 0.05$ ) were intersected with SNPs associated with susceptibility to candidaemia showing a P-value between  $9.99 \times 10^{-5}$  and  $5 \times 10^{-8}$  to identify cQTLs associated with susceptibility.

### QTL mapping of ROS production and *Candida* killing

We selected 137 healthy individuals from 200FG for whom both genotype and measurements of ROS production and *Candida* killing (in percentages) were available. We applied a log2 transformation and rank-based inverse normal transformation on raw measurements of ROS production and *Candida* killing respectively and the correlation between ROS production and *Candida* killing with genotypes was tested by linear regression model with age and gender as co-variables using the R-package Matrix-eQTL. We considered  $P < 0.05$  to be the threshold for significant QTLs.

## Pathway enrichment analysis

We performed gene over-representation analysis using ConsensusPathDB-human database (CPDB; <http://cpdb.molgen.mpg.de/>). The analysis was done using the default settings, where pre-defined lists of functionally associated genes (pathways, Gene Ontology categories and neighborhood-based entity sets) are tested for over-representation in a user-specified list based on the hypergeometric test. For each of the predefined sets, a P-value was calculated according to the hypergeometric test based on the number of physical entities present in both the pre-defined set and the user-specified list of physical entities. P-values were corrected for multiple testing using the false discovery rate method and are available as q-values. To identify independent cQTL loci, linkage disequilibrium (LD) SNP pruning of cQTLs using genotypes extracted from the 500FG cohort was performed based on pairwise genotypic correlation using PLINK 1.90 (<https://www.cog-genomics.org/plink2>), with one of a pair of SNPs removed if LD was  $> 0.2$ . Next, we extracted genes in a window of  $\pm 500$  kb from the twenty-one independent loci and filtered the genes using differential gene expression data of PBMCs in response to *C. albicans* for 4 and 24 hours. Once this had all been done, we finally ran the over-representation analysis.

## Genome-wide case-control association analysis

The associations between the GWAS-identified variants and candidaemia susceptibility were tested by Fisher's exact test using PLINK 1.9 ([www.cog-genomics.org/plink/1.9/](http://www.cog-genomics.org/plink/1.9/))<sup>43</sup>. The genomic inflation factor ( $\lambda = 1$ ) indicated that there was no population stratification effect (Figure S5). A P value significance threshold of  $< 5.0 \times 10^{-8}$  was set to call genome-wide significant associations. We considered SNPs with a P-value between  $9.99 \times 10^{-5}$  and  $5 \times 10^{-8}$  as variants showing a suggestive association with candidaemia susceptibility.

## List of abbreviations

*C. albicans*: *Candida albicans*; *A. fumigatus*: *Aspergillus fumigatus*; *C. neoformans*: *Cryptococcus neoformans*; SNP: single nucleotide polymorphism, cQTL: cytokine-quantitative trait locus

## Declarations

### Ethics approval and consent to participate

All volunteers gave written informed consent prior to blood donations and the study was approved by the ethical review board of Radboud University Nijmegen. The Human Functional Genomics Project (HFGP) was approved by the Ethical Committee of Radboud University Nijmegen, the Netherlands (no. 42561.091.12).

Experiments were conducted according to the principles expressed in the Declaration of Helsinki and venous blood samples were drawn after written informed consent was obtained.

### **Availability of data and material**

The datasets used and/or analyzed during the current study are available from the corresponding author on reasonable request

### **Competing interests**

The authors declare no competing interests.

### **Funding**

This work was supported by a European Research Council (ERC) Consolidator Grant [FP/2007-2013/ERC grant 2012-310372] and a Netherlands Organization for Scientific Research (NWO) Spinoza prize grant [NWO SPI 94-212] to M.G.N., an ERC Advanced grant [FP/2007-2013/ERC grant 2012-322698] and an NWO Spinoza prize grant [NWO SPI 92-266] to C.W., a European Union Seventh Framework Program grant (EU FP7) TANDEM project [HEALTH-F3-2012-305279] to C.W. and V.K., and a Research Grant [2017] of the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) to V.K. Y.L. and M.O. were supported by a VENI grant (863.13.011 and 016.176.006) from the Netherlands Organization for Scientific Research (NWO). V.M. is supported by a PhD scholarship from Graduate School of Medical Sciences, University of Groningen, the Netherlands.

### **Author's contributions**

Conceptualization: M.J., V.M., R.A.G., C.W., M.G.N., V.K.; Methodology: L.A.B., Y.L., C.W., M.G.N., V.K.; Analysis: V.M., M.J., R.A.G., M.S.G., M.O., S.P.S., S.W.I.J.; Data collection: M.J., M.D.J., M.G., M.O., S.P.S., J.R.P., F.L.V., B.J.K., R.J.X., L.A.B.; Data analysis: M.J., V.M., R.A.G., X.C., V.K., Y.L.; Writing: M.J., V.M., M.G.N., V.K.; Project administration: M.G.N., C.W., V.K.; Funding acquisition: M.G.N., V.K., M.O., Y.L. All authors read and approved the manuscript.

### **Acknowledgements**

The authors thank all volunteers from the 500 and 200 Functional Genomics cohort of the Human Functional Genomics Project for participation in the study. The authors would like to thank K. McIntyre for editing the final text.

# Supplementary Information

**Figure S1.** Increased cytokine variation upon stimulation with *C. albicans* yeast and hyphae in WB, PBMCs, and monocyte-derived macrophages. Y-axis depicts the log<sub>2</sub> transformed cytokine levels. X-axis shows stimulation used: *C. albicans* yeast, *C. albicans* hyphae, or the RPMI medium (with or without serum) used as control. Colors in legend indicate the three different cell systems used. Gray: monocyte-derived macrophages, Light blue: peripheral blood mononuclear cells (PBMCs) and Red: whole blood (WB).

**Figure S2.** Shared genetics between *C. albicans* yeast and *C. neoformans*. (A) Barplot shows a significant enrichment of shared cQTLs that affect T-cell-derived cytokines (IFNγ, IL-17A and IL-22) compared to cQTLs that affect monocyte-derived cytokines at different P-value thresholds:  $P < 1 \times 10^{-4}$ ,  $P < 1 \times 10^{-5}$  and  $P < 1 \times 10^{-6}$ .  
Jaeger M. et al.

**Figure S3.** *PLA2G4B* locus was prioritized as a plausible candidaemia susceptibility gene based on differential expression and immunological data. (A) Barplot showing the  $-\log_{10} P$  values of differential expression of *PLA2G4B* upon stimulation with *C. albicans* in PBMCs compared to the RPMI medium used as control. *PLA2G4B* gene expression was significantly decreased after 24-hour stimulation with *C. albicans* ( $P 1.02 \times 10^{-13}$ ). (B) Knockdown efficiency of siRNA experiments of *PLA2G4B* gene upon stimulation of macrophages with *C. albicans* yeast and hyphae. Cytokine production capacity of *TNF $\alpha$* , *IL-1 $\beta$* , *IL-6* and *IL-1Ra* upon specific *PLA2G4B* siRNA, or control siRNA of *C. albicans* stimulated macrophages. Data from three experiments with at least two donors per experiment was pooled.

**Figure S4.** (A) Multidimensional scaling (MDS) analysis (performed in PLINK, on the  $N \times N$  matrix of genome-wide IBS pairwise distance) of candidaemia patients and case-matched controls for the two first principle components. Each dot represents an individual. Green: patients. Yellow: controls. (B) Quantile-Quantile (QQ) plot of association P-values for all SNPs on the genome-wide genotyping array (Black dots). The genetic inflation factor  $\lambda$  for all SNPs was 1, indicating no population stratification.

**Table S1.** Twenty SNPs associated with candidaemia susceptibility (out of seventy-five,  $P < 0.05$ ) modulate multiple cytokines upon stimulation with the two *C. albicans* morphotypes, yeast and hyphae, of any of the three cell systems (WB: whole blood, PBMCs: peripheral blood mononuclear cells, and macrophages).

#### Abstract

Circulatory inflammatory proteins, such as cytokines and chemokines, play a significant role in anti-*Candida* host immune defence. However, little is known about the genetic variation that contributes to the variability of inflammatory responses in response to *C. albicans*. To systematically characterize inflammatory responses in *Candida* infection, we profiled 92 circulatory inflammatory proteins in 42 candidaemia patients. Given the significant differences in inflammatory protein profiles between patient and healthy individuals, we correlated genome-wide single nucleotide polymorphism (SNP) genotypes with protein abundance (QTLs) produced by peripheral blood mononuclear cells, stimulated with *C. albicans* yeast, from 436 individuals of European origin from the 500 Functional Genom-

ics (500FG) cohort in the Human Functional Genomics Project and Lifelines Deep cohort. We identified 10 genome-wide significant protein-QTLs modulated CCL4, VEGF-A, IL-8, CXCL9, MCP-1, MCP-2 and MCP-3 in response to *C. albicans*. Furthermore, we investigated whether differences in susceptibility and survival of candidaemia patients can be explained by modulating levels of inflammatory proteins. Our genetic analysis suggested that there is a distinct genetic contribution between inflammatory responses to *Candida* infection, susceptibility, and survival, indicating a different biology underlying these phenotypes that could provide new therapeutic opportunities.

**Keywords:** inflammatory proteins, protein-QTLs, *C. albicans*, candidaemia, susceptibility, survival

## Introduction

*Candida* species are by far the most common fungal pathogens that cause both invasive and mucosal fungal infections. They have been described as the fourth most common cause of nosocomial bloodstream infection in the United States<sup>1,2</sup>. Invasive candidiasis causes more than 250,000 new systemic infections on a yearly basis and leads to more than 50,000 deaths<sup>3</sup>. Most humans are colonized with *C. albicans* shortly after birth, which remains as part of a normal human's microbiota. Infection occurs only if the epithelial barrier function is impaired and/or there are microbiome imbalances and/or the host immune system is compromised. Under these conditions, *Candida* can invade tissue and reach blood circulation. The bloodstream carries *Candida* to almost all vital organs, leading to systemic infections and, eventually, to organ failure followed by death.

Protective immunity to *Candida* involves both innate and adaptive cellular and humoral responses<sup>4,5</sup>. Cytokines and chemokines are a group of low molecular weight proteins that contribute significantly to anti-*Candida* host immune defence by acting as mediators between immune and non-immune cells, by enhancing the antifungal activity of immune cells and by attracting inflammatory immune cells to the site of infection. Previous studies have shown the capacity of *C. albicans* to induce production of various cytokines and chemokines<sup>6-8</sup>. Some of these proteins in the circulation have also been extensively explored as disease biomarkers to determine onset, progression, patient susceptibility, or predict efficacy of a treatment<sup>9-11</sup>. However, proteins are inherently influenced by genetic and non-genetic factors. Therefore, the identification of these factors would help

to stratify patients based on their risk, and those at high risk would benefit most by prophylactic antifungal treatment or adjunctive immunotherapy.

By studying genetics of only six different cytokines in the context of *Candida*-stimulation, we have shown that SNPs affecting cytokine responses are associated to susceptibility to candidaemia<sup>12–14</sup>, suggesting that modulation of cytokines can determine disease susceptibility. Of note, among candidaemia patients with a combination of several well-described risk factors, the disease prognosis is generally poor and survival rates differ greatly among them, indicating that genetic variation determines patient survival as well<sup>15</sup>. Given that genetic factors regulate the excess levels of proteins in circulation or dysregulated production, which can, subsequently, determine susceptibility and patient survival, it is important to assess the impact of these genetic factors on a wide range of inflammatory proteins in circulation during *C. albicans* infections. In the current study, therefore, we hypothesized that modulation of circulatory inflammatory proteins contributes to susceptibility to candidaemia and patient survival (Fig. 1A). However, all previous studies with *C. albicans* as stimulant studied a narrow spectrum of inflammatory proteins, such as cytokines and chemokines<sup>6–8</sup>, and a systematic study of inflammatory proteins released in the blood circulation upon *C. albicans* and their impact on susceptibility and patient survival is lacking.

Thus, the aims of the present study were to identify (i) the abundance of differentially regulated plasma proteins in circulation of patients (Fig. 1B) (ii) (non)-genetic factors that may influence the abundance of inflammatory proteins in circulation (Fig. 1C and D) and, (iii) finally, to investigate the impact of these genetic loci on susceptibility to candidaemia and patient survival. For this, we profiled 92 inflammatory proteins in the plasma of a candidaemia patient cohort and of two independent population-based cohorts, the 500 Functional Genomics (500FG) cohort within the Human Functional Genomics Project (<http://www.human-function-algenomics.org>) and Lifelines DEEP cohort (<https://www.lifelines.nl/researcher/biobank-lifelines/additional-studies/lifelines-deep>) using the Olink inflammatory array (<http://www.olink.com>).

We observed a significantly different circulatory protein profile in plasma from candidaemia patients compared to healthy individuals. In addition, we identified 10 independent novel protein quantitative trait loci (pQTLs,  $P < 5 \times 10^{-8}$ ). Of note, pQTLs showed a poor enrichment for genetic variants associated with candidaemia susceptibility and patient survival. This finding indicates a distinct genetic contribution in candidaemia susceptibility, patient survival and inflammatory responses in *Candida* infection. We finally investigated whether pQTLs also contribute to other complex infectious diseases.

**Fig. 1.** Overview of our hypotheses and studies. (A) Three scenarios can explain susceptibility to candidaemia and patient survival: (1) Distinct genetic variation ( $SNP_1$  or  $SNP_2$ ) determines susceptibility to candidaemia or patient survival, (2) same genetic variation contribute to the two phenotypes (susceptibility or survival) and (3) the two phenotypes can be determined by modulating the levels of inflammatory proteins (same or different pQTLs) in blood circulation. (B) By obtaining the protein profiling of plasma proteins in candidaemia patients ( $n = 42$ ) and healthy individuals from Lifelines cohort ( $n = 89$ ), we compared the abundance of differentially regulated plasma proteins in blood circulation between patients and healthy subjects. (C) We also studied the effect of non-genetic factors available for 360 individuals from 500FG cohort on the regulation of various inflammatory proteins. (D) In addition to non-genetic factors, we studied the effect of host genetics on the regulation of inflammatory responses by mapping pQTLs in a joint analysis of 500FG ( $n = 360$ ) and Lifelines Deep ( $n = 76$ ) cohorts. For pQTL mapping, we profiled the proteins released from *C. albicans*-stimulated PBMCs isolated from healthy individuals and obtained the imputed genotypes of the studied individuals. Lastly, (E) we investigated whether pQTLs determine susceptibility to candidaemia and patient survival. For this, we used data from our previous GWAS of candidaemia patients ( $n = 178$ ) and case-matched controls ( $n = 175$ ) on candidaemia susceptibility (chapter 3) and, in the current study, we performed a QTL mapping of variants associated with survival. In addition, we tested for association with 14-, 30- and 90-day survival by following up a subgroup of candidaemia patients ( $n = 148$ ), who passed away (1) within 14 days, (2) between 14 and 30 days, and (3) between 30 and 90 days. The rest of the patients ( $n = 83$ ) survived longer than 90 days (survivors). Protein profiling of candidaemia and population-based cohorts were done using the same inflammatory array from OLINK technology. Stimulations of PBMCs with *C. albicans* were performed for 24 hours using *C. albicans* yeast. GWAS: genome-wide association study; QTL: quantitative trait loci; PBMCs: peripheral blood mononuclear cells.

## Results

### Overview of inflammatory responses in candidaemia patients

To systematically study the inflammatory responses in candidaemia patients compared to healthy individuals, we first assessed the abundance of 92 inflammatory proteins in the plasma of 42 candidaemia patients and 89 healthy individuals from the Lifelines DEEP cohort using the OLINK inflammatory array (Fig. 1B). Out of 92 proteins, 64 proteins were included for the differential abundance analysis based on their detectability in at least 90% of the samples tested. A complete list of the proteins measured is provided in Table S1. Significant differences in the levels of the majority of inflammatory proteins were observed in patient plasma samples compared to baseline healthy plasma samples (56 out of 64 proteins with  $P < 0.05$ , Figure S1), indicating a high inflammation status in patients compared to healthy controls. Of the significantly differentially expressed proteins, fifteen inflammatory proteins showed more than 1.5 fold differences (Table S2).

To explore further the co-regulation patterns of plasma proteins in patients compared to healthy individuals, we performed unsupervised clustering of protein responses that were detected in at least 90% of the samples and were expressed in both patients and controls ( $N_{\text{proteins}} = 64$ ). Clustering indicated that there is a clear distinction in inflammatory responses between patients and healthy controls. Ten patients formed a distinct cluster from the rest of the patients and present a similar clustering pattern as healthy controls, with the exception of MMP-1 expression. MMP-1 expression seems to be very strong in all patients compared to controls, suggesting that MMP-1 plays an important role in inflammation in patients (Figure S2).

### Overview of inflammatory protein profiles in PBMCs from healthy individuals in response to *C. albicans* stimulation

By comparing circulatory protein profiles between candidaemia patients and healthy controls, we identified significant differences in inflammatory protein profiles (Figure S1). We, therefore, tested whether some of these proteins are produced by PBMCs in response to *C. albicans* stimulation (Fig. 1D). We obtained PBMCs from 360 individuals of European origin from the 500FG and profiled 92 inflammatory proteins in response to *C. albicans* yeast, of which 32 were detected in at least 90% of the samples (Table S3). Firstly, we compared the abundance of the 32 proteins between stimulated and un-stimulated (using RPMI medium) conditions and observed increased inter-individual variation in inflammatory proteins upon stimulation compared to samples stimulated with RPMI medium (Figure S3). This observation suggested the role of different factors in regulating

the abundance of these proteins.

We could identify up-regulation of 29 proteins out of 32 proteins measured in at least 90% of PBMC samples that show more than 1.5 fold change compared to RPMI stimulated samples (Table S4). In candidaemia patients, we identified 64 proteins measured in at least 90% of the samples, of which 15 showed 1.5 fold difference compared to baseline healthy samples (Lifelines cohort). These observations suggest that, in addition to PBMCs, many other cell types may contribute to the abundance of different proteins in circulation. Next, we compared the correlation structure between the circulatory proteins released from PBMCs by performing an unsupervised clustering of the protein responses. Clustering revealed three distinct clusters (Fig. 2), in which a large cluster consisted of 27 proteins (out

**Fig. 2.** Clustering of inflammatory responses induced in *Candida*-stimulated PBMCs revealed three distinct clusters, with the majority of them organized in a common cluster. The correlation structure of thirty-two proteins, which were detected in at least 90% of the samples, is shown. Unsupervised hierarchical clustering was performed using Spearman correlation as the measure of similarity. The red color depicts the strong positive correlation whereas blue color indicates the strong negative correlation. PBMCs were obtained from 360 individuals from the 500FG cohort and were stimulated with *C. albicans* yeast for 24 hours.

of 32 that were detected in at least 90% of the samples), and two small clusters with only two (IL-8 and MCP-1) and three (CSF-1, MCP-2, and MIP-1 alpha) proteins respectively. To explore if any of these clusters are different in patients, we performed unsupervised clustering of inflammatory proteins released from PBMCs and patients. We observed different clustering patterns of protein responses between PBMC samples and patients (with the exception of one patient) (Figure S4), suggesting the presence of additional factors contributing to the inflammatory responses in patients. MMP-1 expression seems to be stronger in patients compared to 500FG samples, providing more evidence that MMP-1 expression is a distinctive protein signature for patients compared to controls (as mentioned above) and to *Candida*-stimulated PBMCs.

### **Minimal effect of non-genetic host factors and cell counts on inflammatory proteins in response to *C. albicans***

Given the increased inter-individual variation in inflammatory proteins upon *Candida* stimulation (Figure S3), we next aimed to identify whether host non-genetic factors determine these person-to-person differences in inflammatory responses. It is possible that different cell-count proportions in individuals can explain this inter-individual variation. To test whether cell-counts influence the levels of inflammatory proteins, in addition to protein data measured in *Candida*-stimulated PBMCs isolated from the 500FG cohort ( $n = 360$ ), we used the FACS measurements that were previously performed in the same cohort, where different immune cell populations were counted in detail together with non-genetic host factors<sup>16,17</sup>. We analyzed the correlation structure between cell counts (CD14<sup>+</sup> monocytes, CD4<sup>+</sup> T cells, CD3<sup>+</sup>CD56<sup>-</sup> T cells, lymphocytes, CD3<sup>-</sup>CD56<sup>+</sup> NK cells, CD19<sup>+</sup> B cells and CD8<sup>+</sup> T cells) and protein measurements from *Candida*-stimulated PBMCs. We observed weak correlations between cell counts and protein levels, suggesting a minor effect of cell-count differences on protein production capacity (mean correlation coefficient across CD14<sup>+</sup> monocytes = 0.234, CD4<sup>+</sup> T cells = -0.056, CD3<sup>+</sup> CD56<sup>-</sup> T cells = -0.038, lymphocytes = -0.025, CD3<sup>-</sup> CD56<sup>+</sup> NK cell = 0.01, CD19<sup>+</sup> B cells = 0.019 and CD8<sup>+</sup> T cells = 0.011) (Figure S5A).

It has been well established that age and gender influence immune responses<sup>18</sup>. Also, we have previously reported a strong impact of age and gender on the production of six different cytokines (IL-1 $\beta$ , TNF $\alpha$ , IL-6, IFN $\gamma$ , IL-22 and IL-17)<sup>16</sup>. To systematically investigate the impact of non-genetic factors, including age and gender, on the 32 inflammatory proteins released from PBMCs, we correlated age, gender, BMI, oral contraceptive use, and circulating mediators (resistin, adiponectin, alpha-1 Antitrypsin, leptin and CRP) with our proteins. BMI, oral contraceptive use and circulating mediators had no detectable effect on *in vitro*

protein production in PBMCs (Table S5 and S6). In contrast, three of the inflammatory proteins (MMP-1 and CXCL5 and CCL23) were significantly correlated with age ( $P < 0.05$ ) (Figure S5B and Table S5). In addition, TNFRSF9, PD-L1, IL-1 $\alpha$ , IL-18, IL-12B, EN-RAGE, CXCL9 and CSF-1 showed a significant (positive) correlation with gender ( $P < 0.05$ ) (Figure S5B and Table S5).

### **Identifying genetic variation affecting inflammatory proteins in response to *C. albicans***

Next, we investigated whether host genetic variation affects the inter-individual differences in inflammatory responses to *C. albicans* stimulation. For this, we used the genome-wide SNP genotype data and protein measurements of *Candida*-stimulated PBMCs isolated from two population-based cohorts consisting of 360 individuals from the 500FG cohort and 76 individuals from the Lifelines DEEP cohort. Upon quality control and intersection of the proteins from the two cohorts, we obtained a total of 32 inflammatory proteins (Figure S6 and S7 and Table S3 and S7). For pQTL mapping, we selected SNPs that showed a minor allele frequency (MAF)  $\geq 1\%$  and passed other quality filters (see Materials and Methods). Using the protein and genotype data, we mapped protein-QTLs (pQTLs) in the two cohorts and performed a joint analysis by combining the two cohorts ( $n = 436$ ).

In detail, raw protein levels were log2-transformed and then mapped to genotype data using a linear model with age and gender as covariates. Given that a strong influence of age and sex on immunological traits has been previously reported, we used age and gender as covariates on our model<sup>16,19,20</sup>. Our joint analysis revealed 10 independent *trans*-pQTLs with MAF  $> 1\%$  that reached genome-wide significance level ( $P < 5 \times 10^{-8}$  and FDR 0.10) (Table 1, Fig. 3 and Figure S8). These include one independent pQTL for CCL4, one for VEGF-A, two for IL-8, two for CXCL9, one for MCP-1, two for MCP-2 and one for MCP-3 (Fig. 3A-G).

### **Prioritizing *cis*-genes from genome-wide significant pQTLs indicates those involved in hemostasis and lipid metabolism as potential causal genes**

We hypothesized that genes from the genome-wide significant pQTL loci that are differentially expressed in PBMCs in response to *C. albicans* are potential causal genes. To investigate this, we tested the expression levels of all genes located within a 500 kb *cis*-window of the pQTLs in PBMCs stimulated with *C. albicans* at 4 and 24 hours. We identified Wnt family member 5A (*WNT5A*) gene as differentially expressed at both 4 and 24 hours. Single-stranded DNA binding protein 2 (*SSBP2*), family with sequence similarity 151 member B (*FAM151B*) and caspase 7 (*CASP7*) genes were differentially expressed at 24 hours. Of those, *WNT5A* gene

**Fig. 3.** Genome-wide pQTL mapping identified ten *C. albicans* yeast-response pQTLs. Manhattan plot showing the genome-wide QTL mapping results for *C. albicans*-induced (A) CCL4, (B) VEGF-A, (C) IL-8, (D) CXCL9, (E) MCP-1, (F) MCP-2 and (G) MCP-3 levels. The y-axis represents the  $-\log_{10}(p)$  values of pQTLs. Their chromosomal positions are shown on the x axis. The horizontal red dashed line represents the genome-wide significance threshold for association ( $P < 5 \times 10^{-8}$ ).

<sup>a</sup>Proxy SNP (LD  $\geq 0.8$ ) is a missense variant. <sup>b</sup>pQTL or proxies (LD  $\geq 0.8$ ) shows a cis-eQTL effect upon *C. albicans* stimulation in PBMCs ( $P < 0.05$ ). <sup>c</sup>Gene is differentially expressed upon *C. albicans* stimulation at 24 hours. <sup>d</sup>Proxy SNP shows an eQTL effect in blood.

<sup>e</sup>Gene is differentially expressed upon *C. albicans* stimulation at 4 hours. <sup>f</sup>Gene is in close proximity to pQTL.

MAF: Minor allele frequency in the 500FG and Lifelines DEEP cohorts, Chr: chromosome, BP: base-pairs

belongs to the WNT gene family that signals through both the canonical and non-canonical WNT pathways. Of note, the Wnt/ $\beta$ -Catenin signaling pathway exerts immunomodulatory functions during inflammation and infection<sup>21,22</sup>. The other prioritized gene, *CASP7*, a member of the cysteine-aspartic acid protease (caspase) family, is involved in the activation cascade of caspases that are critical molecules in apoptosis, necrosis, and inflammation<sup>23</sup>.

In addition, to identify causal genes, we made use of publicly available expression-QTL datasets (eQTLs) from healthy blood donor samples<sup>24,25</sup>. We identified a proxy SNP rs4682062 in strong linkage disequilibrium (LD) with rs1398749 on chromosome 3 ( $r^2 > 0.8$ ; using the European population as a reference) to influence the expression of two genes, the abhydrolase domain containing 10 (*ABHD10*,  $P 1.58 \times 10^{-27}$ ) and *CD96* ( $P 1.50 \times 10^{-5}$ ) genes, in whole blood. *CD96* gene encodes a protein (also known as TACTILE) that belongs to immunoglobulin superfamily and negatively controls cytokine production by natural killer (NK) cells<sup>26</sup>. The *ABHD10* gene encodes for an enzymatic degrader of mycophenolic acid acyl-glucuronide<sup>27</sup>. In general, the mammalian alpha beta hydrolase domain (ABHD) proteins have been recently described as novel potential regulators of lipid metabolism and signal transduction<sup>27</sup>. Given that eQTL effects may act in a context-specific manner<sup>28</sup>, we also mapped *Candida*-response eQTLs. Three SNPs in high linkage disequilibrium ( $LD \geq 0.8$ ) with pQTL rs2501301 on chromosome 1, influence the expression of a non-coding RNA, *CDC42-IT1*, and pQTL rs392422 on chromosome 5 influences another non-coding RNA, *CTC-281B15.1* in response to *C. albicans* (Table 1).

Lastly, pathway enrichment analysis of *Candida*-induced pQTLs with a  $P$  value  $< 9.99 \times 10^{-4}$  showed an over-representation of genes involved in hemostasis ( $P 8.99 \times 10^{-5}$ ) and metabolism of lipids and lipoproteins ( $P 2.47 \times 10^{-3}$ ) (Figure S9), indicating the importance of hemostasis and lipid metabolism in anti-*Candida* inflammatory responses.

### Pleiotropy of loci affecting protein levels

To test the presence of potential pleiotropic effects between the GWAS pQTLs identified in the joint analysis and measured proteins, we performed an unsupervised clustering of pQTLs based on the negative log10 of the  $P$  values. For this analysis, we extracted all possible associations of genome-wide significant pQTLs with the 32 proteins in the same allelic direction between the two cohorts and  $P$  value of heterogeneity  $\geq 0.05$ . We observed that all genome-wide significant loci influence multiple distinct proteins (Fig. 4A), indicating the pleiotropic effects of the pQTLs on the proteins. To account for multiple testing, we next inspected all genome-wide significant *trans*-pQTLs that had at least two associations with dis-

tinct proteins at  $P < 0.05/(10 \times 32) = 1.56 \times 10^{-4}$  (Table S8). This cut-off represents a conservative approach to correct for multiple testing for all identified GWAS SNPs ( $n = 10$ ) with all protein traits ( $n = 32$ ). SNP rs248863 was removed as it influences only MCP-2 at  $P$  threshold of  $1.56 \times 10^{-4}$ . We observed a locus at intergenic variant rs6771739 on chromosome 3 and a second locus at intronic variant rs34774255 on chromosome 7 that influences 17 and 11 distinct proteins respectively at  $P < 1.95 \times 10^{-4}$  in the same direction (Fig. 4B to C, and Figure S10). Of note, both loci influence the levels of CXCL9 *in trans*, indicating that this chemokine may have a key regulatory role in inflammation in response to *C. albicans* infection.

Moreover, two loci at intergenic variant rs358011 (Fig. 4D) and intronic variant rs247426 (Fig. 4E) on chromosomes 3 and 16 respectively influence six distinct proteins each in the same direction. The variant rs358011 influences the inflammatory protein VEGF-A and the rs247426 influences MCP-3 *in trans* at a genome-wide significance level (Table 1, Figure S10). These pleiotropic effects suggest that MCP-3 and VEGF-A may have important roles in inflammation induced by *C. albicans*. Lastly, unsupervised clustering revealed that different loci influence same proteins in opposite direction (Figure S10). For instance, the locus at intronic variants rs1699130 on chromosome 8 increases the expression of MCP-1 and IL-8 and two loci at intronic variants rs1398749 and rs392422 on chromosomes 3 and 5 respectively show an opposite effect. In addition, the locus at intronic variants rs247426 on chromosome 16 increases the expression of MCP-2 and MCP-3 and a different locus at rs1572285 on chromosome 10 decreases their expression. However, more studies are needed to explain the mechanism by which these opposite effects occur.

### Contribution of pQTLs that influence circulatory inflammatory proteins to susceptibility and survival to candidaemia

Next, we aimed to investigate whether genetic variation that influences inflammatory proteins (pQTLs) in blood circulation may determine susceptibility and survival to candidaemia. We previously performed the first GWAS on the largest candidaemia cohort to date to identify genetic variants that determine susceptibility to candidaemia (*chapter 3*). The candidaemia cohort consisted of 178 patients and 175 case-matched controls. To investigate the contribution of pQTLs to candidaemia susceptibility, we performed enrichment analysis of pQTLs for susceptibility variants. For this, we grouped the pQTLs identified in the joint analysis at four different  $P$  thresholds ( $5 \times 10^{-4}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-6}$ , and  $5 \times 10^{-7}$ ) and extracted the  $P$  values of association to candidaemia susceptibility for each group of pQTLs. We observed that there is a poor enrichment of pQTLs in susceptibility variants at all four different  $P$  thresholds. (Fig. 5A to D). These results suggest that there is a dis-

**Fig. 4.** Potential pleiotropy between genome-wide significant pQTLs and measured inflammatory proteins. Heat-map (A) shows the  $-\log_{10}(P)$  of all possible associations of the genome-wide significant pQTLs and the 32 measured inflammatory proteins, which show the same allelic directions between 500FG and Lifelines Deep cohorts, and  $P_{\text{heterogeneity}} \geq 0.05$ . Regional association plots showing the  $-\log_{10}P$  for SNPs centered on the most strongly associated signal (purple diamond) at (B) rs6771739 associated with CXCL9 levels, (C) rs34774255 associated with CXCL9 levels, (D) rs358011 associated with VEGF-A and (E) rs247426 associated with MCP-3 levels upon *C. albicans* yeast stimulation of PBMCs.

**Fig. 5.** A distinct genetic contribution between candidaemia susceptibility and inflammatory protein responses upon *Candida* stimulation was observed. pQTLs identified in the joint analysis between 500FG and Lifelines DEEP cohorts were grouped at four different P thresholds ( $5 \times 10^{-4}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-6}$  and  $5 \times 10^{-7}$ ) and P values of association with susceptibility to candidaemia were extracted and plotted for each group (y axis). Axis x shows the 32 inflammatory proteins measured in PBMCs in response to *Candida* stimulation. Violin plots show the distribution of P values of association with susceptibility for each different threshold for pQTL effect. The black line within the box plots indicates the median and the dashed black line represents a P value of significance 0.05. pQTLs above the dashed line were considered to be significantly associated with candidaemia.

tinct genetic contribution between candidaemia susceptibility and inflammatory protein responses upon *Candida* stimulation.

In addition, to determine genetic variants that are associated with survival, we performed a within-case QTL mapping on a genome-wide scale by assigning the Matzaraki V. et al.

actual day of survival as quantitative trait using a cohort of 148 candidaemia patients, which was followed prospectively for up to 90 days and mortality dates were recorded. Out of 148 patients, 65 did not survive (non-survivors) within a period of 90 days and 83 patients survived longer than 90 days (survivors). For QTL mapping, we used the genotype and survival data of only 65 non-survivors, of which 31 passed away within 14 days, 18 passed away between 14 and 30 days and 16 passed away between 30 and 90 days, as described in Materials and Methods. This analysis showed a common, intergenic genetic variant ( $\text{MAF}_{1000\text{G}} = 0.2$ ), rs12565126, on chromosome 1 that reached genome-wide significance ( $P 1.8 \times 10^{-10}$ ) (Fig. 6A and B). To examine the effect of SNP genotypes of rs12565126 on survival, we compared differences between SNP genotype strata using a log-rank test by stratifying the 65 non-survivors and 83 survivors by SNP genotype. No significant difference in survival was observed between the different genotype strata. However, Kaplan-Meier plot showed that individuals carrying the T allele tend to have an increased probability to survive longer compared to those homozygotes for CC allele (Fig. 6C).

Furthermore, to test whether the genome-wide significant rs12565126 is associated with early or late survival (up to 90 days), we performed a case/control association analysis with 14-, 30- and 90-day survival on a genome-wide scale. To test for association (1) with 14-day survival, we used 31 non-survivors that passed away within 14 days and 83 survivors, with (2) 30-day survival, we used 49 non-survivors that passed away within 30 days and 83 survivors and with (3) 90-day survival, we used 65 non-survivors that passed away within 90 days and 83 survivors. We run an additive model using gender and the first two principal components as covariates. These analyses showed that rs12565126 was significantly associated with 14-day survival ( $P 0.03$ , OR 6.9) and 30-day survival ( $P 0.02$ , OR 3.6). We did not observe a significant association with 90-day survival at a  $P$  threshold for significance  $< 0.05$  ( $P = 0.54$ ).

Lastly, to investigate the contribution of pQTLs to survival, we performed enrichment analysis of pQTLs for variants associated with survival as identified in the quantitative analysis. For this, we followed the same approach as in enrichment analysis of pQTLs for candidaemia susceptibility, and we grouped the pQTLs at four different  $P$  thresholds ( $5 \times 10^{-4}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-6}$ , and  $5 \times 10^{-7}$ ) and extracted the  $P$  values of association with survival for each group (Fig. 7). We observed that there is a poor enrichment of pQTLs in variants associated with survival. All in all, our enrichment analysis of pQTLs for variants associated with susceptibility and survival showed that distinct genetic variation contributes to the three phenotypes studied here: inflammatory responses upon *Candida* stimulation, susceptibility to candidaemia and patient survival.

**Fig. 6.** QTL mapping results for patient survival. (A) Manhattan plot of the log10 P values identified in the genome-wide QTL mapping on survival using 65 candidaemia patients (non-survivors). Each dot represents a SNP and all analyzed SNPs are plotted on the X-axis ordered by chromosomal position. SNP rs12565126 at chromosome 1 reached genome-wide significance level (shown in red,  $P < 5 \times 10^{-8}$ ). (B) Regional association plot at rs12565126 locus associated with survival. The corresponding P values (as  $-\log_{10}$  values) of all SNPs in a window of 500kb around the genome-wide significant SNP (purple diamond) were plotted against their chromosomal position. Estimated recombination rates are shown in blue to reflect the local LD structure, based on the European (CEU) population, around the associated top SNP and its correlated proxies are shown in a color scale. Highly correlated SNPs are shown in red and the rest of the colors represent weakly correlated SNPs. (C) Kaplan-Meier plot using 65 non-survivors and 83 survivors stratified by the SNP genotypes of rs1256512. Gender used as covariate. The lines represent survival curves of the two-genotype strata (CC , TC+TT). At time zero, the survival probability is 1.0 (or 100% of the patients are alive). The numbers of patients that are still alive through time are shown in parentheses in the bottom plot.

**Contribution of pQTLs that influence circulatory inflammatory proteins to complex infectious diseases**

Given that the genome-wide pQTLs in response to *Candida* infection showed pleiotropy, we next investigated whether genetic variants that were previously associated with other infectious diseases are pQTLs. For this, we selected infectious diseases that showed at least ten independent associations per study in European populations, which are reported in the National Human Research Institute GWAS catalogue (<https://www.ebi.ac.uk/gwas/>). Next, we identified all pQTLs that were associated with inflammatory proteins at  $P \leq 0.001$  and P value for heterogeneity  $\geq 0.05$  and tested whether SNPs associated with infectious diseases or their prox-

Matzaraki V. et al.

**Fig. 7.** A distinct genetic contribution between patient survival and inflammatory protein responses upon *Candida* stimulation was observed. Same approach was followed as described in Fig. 5. pQTLs at four different P thresholds ( $5 \times 10^{-4}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-6}$  and  $5 \times 10^{-7}$ ) showed a poor enrichment for variants associated with survival. Axis x show the 32 inflammatory proteins measured in PBMCs in response to *Candida* stimulation and y axis represents the neg log10 of P values of association with survival. Violin plots show the distribution of P values of association with survival for each different threshold for pQTL effect. The black line within the box plots indicates the median and the dashed black line represents a P value of significance 0.05. pQTLs above the dashed line were considered to be significantly associated with patient survival.

ies ( $r^2 > 0.8$ ) were also pQTLs. We found seven intronic SNPs or proxies ( $r^2 \geq 0.8$ ) associated with infectious diseases that were also pQTLs. Two loci were associated with cytomegalovirus antibody response, another two loci with severe influenza A (H1N1) infection, one locus with hepatitis B, one locus with acquired immunodeficiency syndrome (AIDS) progression and one locus associated with yeast infection (vulvovaginal candidiasis) (Table S9)<sup>33,34</sup>. When using more stringent

P values to call pQTLs, the number of disease-associated SNPs that were pQTLs was dropped to few SNPs ( $n < 10$ ) as the number of available pQTLs was reduced. These preliminary results indicate that inflammatory proteins studied here have an important role as underlying mediators in other infectious diseases as well.

## Discussion

---

The incidence of opportunistic invasive fungal infections has been increased over the last decades. This increase can be explained by the use of aggressive and intensive chemotherapeutic regimens, of immunosuppressive therapy for autoimmune disorders, and of transplantation that have led to a rise in the number of susceptible human hosts<sup>35</sup>. The development of specific and mechanistically relevant biomarkers in *Candida* infections are important tools in identifying patients at high-risk and, thus, clinicians can provide the most beneficial prophylactic and/or treatment strategy. In this study, we performed a systematic proteomic analysis of 92 inflammatory-related proteins in blood circulation in response to *Candida* infection. To our knowledge, this is the first effort to date to evaluate a great number of inflammatory proteins and evaluate the role of host (non)-genetics in regulating inflammatory protein levels in *Candida* infection.

We observed significant differences in inflammatory responses in candidaemia patients compared to healthy individuals from Lifelines cohort. Also, we observed increased inter-individual variation in inflammatory responses in PBMCs stimulated with *C. albicans* compared to samples stimulated with RPMI medium. When comparing the clustering pattern of inflammatory responses between patients and healthy controls, we observed different clustering patterns, as expected. Of note, MMP-1 expression was stronger in patients compared to controls. MMP-1 belongs to the family of matrix metalloproteinases (MMPs) that act as processing enzymes that cleave most structural extracellular matrix (ECM) proteins but, also, cell surface receptors, cytokines, chemokines, clotting factors, cell-cell adhesion molecules, and other proteinases<sup>36</sup>. Previous studies indicated that MMPs play a critical role in the host defence against infection and, of particular interest, can be used as drug targets in infections caused by gram-negative bacteria and in septic shock<sup>37</sup>. Furthermore, we observed different clustering patterns of inflammatory responses between patients and *Candida*-stimulated supernatants of PBMCs, suggesting the presence of additional factors that contribute to the inflammatory responses in patients that are missing in PBMC fraction. These factors could be different cell types (e.g. neutrophils) or blood coagulation factors and platelets that may interact with the inflammatory proteins that are not present in the PBMC fraction.

To explain the observed inter-individual variations in inflammatory responses, we investigated the contribution of (non)-genetic factors to inflammatory responses. Although age and gender has a well-described influence on cytokine responses, correlation analysis of non-genetic factors measured in 500FG cohort with the inflammatory responses showed minimal effect, with few exceptions. Three inflammatory proteins (MMP-1, CXCL5 and CCL23) were significantly correlated with age ( $P < 0.05$ ) and TNFRSF9, PD-L1, IL-1 $\alpha$ , IL-18, IL-12B, EN-RAGE, CXCL9, and CSF-1 showed a significant (positive) correlation with gender ( $P < 0.05$ ) (Figure S6 and Table S5).

In addition, we identified 10 independent significant pQTLs with MAF  $> 1\%$  that reached genome-wide significance level ( $P < 5 \times 10^{-8}$ , FDR 0.10) that influence CCL4, VEGF-A, IL-8, CXCL9, MCP-1, MCP-2 and MCP-3. These pQTLs are *trans*-pQTLs that influence inflammatory responses indirectly through regulatory loops. Pathway enrichment analysis of *Candida*-induced pQTLs with a  $P$  value  $< 9.99 \times 10^{-4}$  showed an over-representation of genes involved in hemostasis and metabolism of lipids and lipoproteins (Figure S9), indicating the importance of hemostasis and lipid metabolism in anti-*Candida* inflammatory responses. Of note, we previously observed that stimulation of PBMCs with *C. albicans* yeast induces transcription of genes involved in inflammation, as expected, and immune-hemostasis interaction (chapter 2). Furthermore, we showed that *Candida*-induced cytokine-QTLs (cQTLs) in PBMCs that are associated with candidaemia susceptibility are enriched in lipid metabolism processes (chapter 3). Altogether, hemostasis and lipid metabolism seem to play a critical role in *Candida*-induced inflammatory responses and, thus, it would be interesting to further investigate their role in host immune defence against *C. albicans*.

To study the concordance of genetic effects on circulating proteins and expression levels in response to *C. albicans*, we also mapped *Candida*-response *cis*-eQTLs in PBMCs. The genome-wide significant pQTL rs392422, which influences IL-8, seems to affect the expression of a gene belonging to the non-coding RNA class, *CTC-281B15.1* (ENSG00000247572) ( $P$  0.03). Also, three SNPs (rs191505409, rs187581857 and rs149399639), which are in high LD  $\geq 0.8$  with the genome-wide significant pQTL rs2501301, affect the expression of the non-coding RNA, *CDC42-IT1* (ENSG00000230068) in response to *C. albicans* ( $P$  0.03, 0.009 and 0.009 respectively). The role of non-coding RNAs in regulating inflammation, including well-known mediators, such as TNF $\alpha$ , IL-1, IL-6, and IL-8 has been previously described<sup>44</sup>, and, thus, we assume that regulation of inflammation during *C. albicans* infection can happen at the transcriptional level through non-coding RNAs and at translation level as well.

Another interesting finding of this study was that the genome-wide significant

*trans*-pQTLs showed pleiotropic effects. In particular, a locus at chromosome 3 and a second locus at chromosome 7 influence 17 and 11 distinct proteins respectively at  $P < 1.56 \times 10^{-4}$  in the same direction. Both loci regulate different factors, such as various pro-inflammatory cytokines and chemokines, vascular endothelial growth factors (VEGF-A), pro-inflammatory mediators with effects on endothelial cells (OSM)<sup>45</sup> and transforming growth factors (TGF- $\alpha$ ) (Table S8). This observation reflects the fact that an inflammatory response is the result of complex interactions between inflammatory and endothelial cells that can be regulated by the same genetic variation. In addition, we observed that SNPs associated with other complex infectious diseases, such as influenza A (H1N1) infection, hepatitis B, AIDS, vulvovaginal candidiasis and cytomegalovirus antibody response, were also pQTLs, highlighting the role of inflammatory proteins as critical mediators in many complex infectious diseases.

Moreover, we investigated the contribution of pQTLs to candidaemia susceptibility and patient survival. We observed a poor enrichment of pQTLs with SNPs associated with candidaemia susceptibility and survival. This finding suggests that distinct genetics determines circulatory inflammatory protein responses during *Candida* infection, candidaemia susceptibility and patient survival. This observation agrees with previous studies on other diseases, such as Crohn's disease, where distinct genetic contributions to prognosis and susceptibility were identified<sup>46</sup>. Another interesting finding of the within-case QTL mapping using 65 non-survivors revealed a genome-wide significant SNP (rs12565126) on chromosome 1 that is associated with survival. Despite the limited number of our survival cohort ( $n = 148$ ), Kaplan-Meier analysis showed that individuals carrying the T allele (rs12565126) tend to survive longer compared to homozygotes for the C allele (Fig. 6C).

There are also limitations to our study. First, because of relatively small sample size, we cannot exclude that some of the pQTLs with rare allele frequencies were false positives in this analysis. In addition, the experimental setup of *ex vivo* PBMC stimulation for 24 hours with *C. albicans* yeast provides only the opportunity to study the interactions between immune cells, such as monocytes, T and B cells, missing the neutrophils and platelet fractions. Also, the time-dependent dynamic interactions are missing as PBMCs were stimulated for 24 hours. Lastly, it would be interesting to capture inflammatory responses upon stimulation with *C. albicans* hyphae as well, as the transition to hyphae contributes to *C. albicans* virulence. Despite these limitations, we provided an important groundwork by performing a comprehensive analysis of (non)-genetic variation that affects circulatory inflammatory responses in human blood circulation in response to *C. albicans* that can trigger critical future work to understand better the contribution of genetics to inflammatory responses against *C. albicans* and how it shapes sus-

ceptibility and survival in candidaemia patients.

## Materials and Methods

---

### Study populations

#### *Population-based cohorts*

**500FG.** To understand the variation in circulating inflammatory production (*in vitro*) in response to *C. albicans*, we used a population-based cohort, the 500FG, composed of 534 well-characterized healthy individuals of Western European ancestry. This cohort is part of the Human Functional Genomics Project (HFGP, see [www.humanfunctionalgenomics.org](http://www.humanfunctionalgenomics.org)). The 500FG cohort is composed of 237 males and 296 females all between 18 and 75 years old. The HFGP study was approved by the Ethical Committee of Radboud University Nijmegen, the Netherlands (no. 42561.091.12). Experiments were conducted according to the principles expressed in the Declaration of Helsinki and venous blood samples were drawn after written informed consent was obtained.

**Demographic Data collection in 500FG.** Volunteers, after donating blood in the hospital, received an extensive online questionnaire about lifestyle, diet, and disease history. Based on the results of this questionnaire, 45 volunteers were excluded for various reasons, e.g., they were under medication, non-European ancestry, or had a chronic disease. These exclusion criteria were taken to minimize false positive effects on the protein production capacity *in vitro*.

**Lifelines DEEP cohort.** Adult participants were enrolled from Lifelines, a large general population cohort in the Netherlands, after giving informed consent, following an institutional review board protocol approved by the University Medical Centre Groningen (Groningen, the Netherlands). The study design of Lifelines DEEP (i.e. DEEP: Detailed Extensive Examination of Participants) has been described elsewhere (<http://lifelines.nl/researcher/biobank-lifelines/additional-studies/lifelines-deep>).

**Patient cohort.** Adult candidaemia patients were enrolled after informed consent (or waiver as approved by the Institutional Review Board) at the Duke University Hospital (DUMC, Durham, North Carolina, USA). Enrollment occurred between January 2003 and January 2009 and, in total, 178 candidaemia cases and 175 case-matched controls of European ancestry were tested for disease association. The demographic and clinical characteristics of the candidaemia cohort have been described previously<sup>47</sup>. Patients must have had at least one positive blood culture for a *Candida* species, with the majority of them infected by *C. albicans*<sup>47</sup>. Case-

matched controls were recruited from the same hospital wards as candidaemia cases so that co-morbidities and clinical risk factors for infection were similar. One hundred forty-eight (148) candidaemia patients at DUMC were followed prospectively for up to 90 days and mortality dates were recorded for these individuals. Thirty-one out of 148 passed away within 14 days, 18 out of 148 passed away between 14 and 30 days and 16 out of 148 individuals passed away between 30 and 90 days (non-survivors). Eighty-three out of 148 individuals survived longer than the specified period of 90 days and we defined them as survivors in this study.

### **Genotyping, quality control and imputation of the 500FG cohort**

DNA obtained from the 500FG cohort was genotyped using the commercially available Illumina HumanOmniExpressExome-8 v1.0 SNP chip. Genotype calling was performed using Optical 0.7.0 using default settings<sup>48</sup>. We applied quality control per sample to exclude samples with a call rate  $\leq 0.99$  and quality control per SNP to exclude variants with a Hardy-Weinberg equilibrium  $\leq 0.0001$ , a call rate  $\leq 0.99$  and a minor allele frequency (MAF)  $\leq 0.001$ . We identified 17 ethnic outliers by merging multi-dimensional scaling plots of samples with 1000 Genomes data, and these outliers were excluded from further analysis<sup>12</sup>. The quality control filters resulted in a dataset of 483 samples containing genotype information on 518,980 variants for further imputation. The strands and variants-identifiers were aligned to the reference Genome of the Netherlands (GoNL, Genome of the Netherlands Consortium, 2014<sup>49</sup>) dataset using Genotype Harmonizer<sup>50</sup>. The data were phased using SHAPEIT2 v2 using GoNL as a reference panel<sup>51,52</sup>. We selected SNPs that showed an INFO score  $\geq 0.8$  upon imputation for further cytokine QTL mapping.

### **Genotyping, quality control and imputation of the candidaemia cohort**

Isolated DNA obtained from case and control samples was genotyped using the commercially available SNP chips, HumanCoreExome-12 v1.0 and HumanCoreExome-24 v1.0 BeadChip from Illumina (<https://www.illumina.com>). Genotype calling was performed using Optical 0.7.0 using the default settings<sup>48</sup>. Strands of variants were aligned and identified against the 1000 Genome reference panel using Genotype Harmonizer<sup>50</sup>. We then imputed the samples on the Michigan imputation server using the human reference consortium as a reference panel, and we filtered variants with an  $R^2$  of 0.3 for imputation quality<sup>53</sup>. After excluding imputed variants with a MAF  $< 0.10$  and variants within the HLA region, we applied quality control per sample and removed 15 individuals (5 cases and 10 controls) due to excess/reduced heterozygosity and cryptic relatedness. Next, we applied SNP quality control filters to exclude SNPs with a MAF of  $< 0.05$  and a Hardy-Weinberg equilibrium of  $P < 1 \times 10^{-6}$  in control samples only. We also

identified 25 ethnic outliers (12 cases and 13 controls) by multidimensional scaling analysis (MDS) (performed in PLINK on the  $N \times N$  matrix of genome-wide IBS pairwise distance) of candidaemia patients and case-matched controls for the two first principle components (Figure S11A). The quantile-quantile (QQ) plot that shows the distribution of the observed  $-\log_{10}$  for the whole-genome SNPs against the theoretical distribution of expected  $-\log_{10}$  indicated no or little evidence of population stratification (Figure S11B). The genomic inflation factor based on median  $\chi^2$  was equal to 1 ( $\lambda = 1$ ). Quality control filters resulted in a dataset of 161 cases and 152 disease-matched control samples containing genotype information on 5,326,313 SNP variants for further testing for association with candidaemia susceptibility.

### **Genotyping, quality control and imputation of the Lifelines DEEP cohort**

Genotyping and genotype imputation of the Lifelines DEEP cohort have been published elsewhere<sup>54</sup>. DNA isolation was performed by the Qiagen robots using Autopure LS kits. Genotyping of DNA from the LifeLines DEEP cohort was performed using both the HumanCytoSNP-12 BeadChip and the ImmunoChip platforms (Illumina, San Diego, CA, USA). First, SNP quality control was applied independently for both platforms where SNPs were filtered on MAF above 0.001, a Hardy-Weinberg equivalent P value  $>1e^{-4}$  and a call rate of  $>0.98$  using Plink<sup>55</sup>. The genotypes generated from both platforms were merged into one dataset. After merging, SNPs were again filtered on MAF 0.05 and a call rate of 0.98, resulting in a total of 379,885 genotyped SNPs. Next, genotypes were imputed using the Genome of the Netherlands (GoNL) reference panel<sup>56–58</sup>. The merged genotypes were pre-phased using SHAPEIT2 and aligned to the GoNL reference panel using Genotype Harmonizer (<http://www.molgenis.org/systemsgenetics/>) in order to resolve strand issues<sup>50</sup>. Imputation was performed using IMPUTE2 version 2.3.0 against the GoNL reference panel<sup>59</sup>.

### **PBMC collection and *Candida* stimulation experiments**

Venous blood from the cubital vein of healthy volunteers was drawn in 10 ml EDTA Monoject tubes (Medtronic, Dublin) after obtaining written informed consent. PBMC isolation was performed as previously described<sup>60</sup>. In short, the PBMC fraction was obtained using density centrifugation of EDTA blood diluted 1:1 in pyrogen-free saline over Ficoll-Paque (Pharmacia Biotech, Uppsala). Cells were then washed twice in saline and suspended in RPMI medium supplemented with gentamicin (10 mg/mL), L-glutamine (10 mM) and pyruvate (10 mM). Addition of antibiotics such as gentamycin is a standard method used to avoid contamination of cultures, and it does not influence the ability to induce cytokine production by PBMCs or macrophages (data not shown). PBMCs were counted in a Coulter counter (Beckman Coulter, Pasadena) and re-suspended in a con-

centration of  $5 \times 10^6$  cells/mL. A total of  $5 \times 10^5$  PBMCs were added in 100  $\mu$ L to round-bottom 96-well plates (Greiner) and incubated with 100  $\mu$ L of stimulus (heat killed *Candida albicans* yeast of strain ATCC MYA-3573, UC 820,  $1 \times 10^6$ /mL) or RPMI medium. After 24 hours, the supernatants were collected and stored at  $-20^\circ\text{C}$  until assayed using commercial available ELISA kits (PeliKine Compact or R&D Systems) or, OLINK technology for high-throughput protein profiling (<https://www.olink.com/>).

### Proteomic profiling of circulating inflammatory proteins

Supernatant samples of PBMCs stimulated with *C. albicans* yeast (obtained from 500FG and Lifelines DEEP cohorts) and plasma samples obtained from candidaemia patients and healthy individuals from Lifelines cohort were analyzed using the proximity extension assay (PEA). We selected the Olink® inflammatory panel (Olink Bioscience AB, Uppsala, Sweden). This panel includes 92 inflammatory proteins. The protein analysis is reported as Normalized Protein Expression (NPX) values, which are Cq values normalized by the subtraction of values for extension control, as well as inter-plate control. The scale is shifted using a correction factor (normal background noise) and reported in Log2 scale. The normality test performed on both raw and log-transformed data using Shapiro-Wilk normality test, and a  $P > 0.05$  was used as a threshold for normal distribution. We further validated the correlation between protein concentrations of IL-6 measured by OLINK technology in log2 picogram/ml (NPX values) and by ELISA (Figure S12). We used Spearman's correlation as the measure of similarity between the two measurements.

### Clustering Analysis

To analyze the similarities and dissimilarities between the measured inflammatory proteins in PBMC supernatants and plasma samples, we performed unsupervised hierarchical clustering using Spearman's correlation as the measure of similarity. To identify whether different cell counts in PBMC fraction have an impact on the circulating proteins, we obtained cell count data measured by FACS for total lymphocytes, T cells, B cells, monocytes and NK-cells from 487 individuals from the 500FG cohort, as previously described<sup>17</sup>. Then, we tested the correlation between cell counts in log2 scale with NPX using Spearman's correlation as the measure of similarity. All statistical analyses regarding the protein data were performed in R version 3.3.2 (<https://www.R-project.org/>).

### Protein QTL mapping

We performed a joint analysis of pQTLs by combining two different population-based cohorts (500FG and Lifelines DEEP cohorts). Lack of protein measurements for all available individuals restricted us to select 360 individuals from

500FG and 76 samples from Lifelines DEEP cohort for whom both genotype and protein data were available. The number of proteins measured in at least 90% of the PBMC samples in 500FG (Table S3) and Lifelines (Table S7) was 32 and 46 respectively. For mapping, we selected proteins that were detected in both cohorts in at least 90% of the samples and, upon quality control of protein distribution (Figure S7 and S8), we obtained a total of 32 inflammatory proteins (Table S3 and S7). Shapiro test was used to test for normality under the null hypothesis that the protein distribution is normal. If  $P$  value  $< 0.05$ , the distribution is non-normal. The majority of proteins expressed in PBMCs from 500FG followed a non-Gaussian distribution, with the exception of three proteins, CD40, VEGF-A and TNFRSF9 (Figure S7 and Table S3). Non-Gaussian distribution was also observed for proteins expressed in PBMCs from Lifelines DEEP cohort, with the exception of few proteins (Figure S8 and Table S7).

To correct the protein distributions for QTL mapping, we used a linear model adjusting for age and gender. NPX values of protein levels were used and the correlation between protein production and genotype was tested independently for both cohorts using the R-package Matrix-eQTL<sup>61</sup>. To jointly test the effect of genetic variation on protein levels measured in both 500FG and Lifelines DEEP cohorts, we used METAL (<http://www.sph.umich.edu/csg/abecasis/metal/>) and removed pQTLs with opposite direction and those that show significant heterogeneity ( $P < 0.05$ ) between the two cohorts<sup>62</sup>. We considered  $P < 5 \times 10^{-8}$  to be the threshold for genome-wide significant pQTLs.

### Measurements of circulating mediators & correlation analysis of non-genetic factors

The circulating mediators resistin, leptin, adiponectin, CRP and alpha-1 antitrypsin (AAT) were measured in EDTA plasma using the R&D Systems DuoSet ELISA kits following the Manufacturer's protocol. To identify the effect of non-genetic factors, such as age, gender, BMI, oral contraceptive use and circulating mediators (resistin, adiponectin, alpha-1 Antitrypsin, leptin and CRP) on levels of circulatory inflammatory proteins in 500FG, we performed a rank-based regression analysis using "Rfit", as previously described<sup>16</sup>.

### Pleiotropy

To test all reported genome-wide significant pQTLs for pleiotropy, we initially inspected all genome-wide significant *trans*-pQTLs whether they show association with multiple distinct proteins. To correct for the multiple testing burden for all genome-wide pQTLs, we next inspected all genome-wide significant *trans*-pQTLs that had at least two associations with distinct proteins at  $P < 0.05/(10 \times 32)$

$= 1.56 \times 10^{-4}$ . This cut-off represents a conservative approach to the multiple testing burden for all identified GWAS SNPs ( $n = 10$ ) with all protein traits ( $n = 32$ ). The resulting association matrix was then clustered and visualized based on the negative log10 of the P values of association. For clustering analysis, we used an unsupervised clustering approach using Spearman's correlation as the measure of similarity.

### RNA sequencing, expression analysis and eQTL mapping

RNA sequencing data from PBMCs of eight individuals stimulated by *C. albicans* were generated and published elsewhere<sup>63</sup>. Sequencing reads were mapped to the human genome using STAR (version 2.3.0)<sup>64</sup>. The aligner was provided with a file containing junctions from Ensembl GRCh37.71. Htseq-count of the Python package HTSeq (version 0.5.4p3) was used (The HTSeq package, <http://www-huber.embl.de/users/anders/HTSeq/doc/overview.html>) to quantify the read counts per gene based on annotation version GRCh37.71, using the default union-counting mode. Differentially expressed genes were identified by statistics analysis using DESeq2 package from bioconductor<sup>65</sup>. The statistically significant threshold (FDR  $P \leq 0.05$  and fold change  $\geq 2$ ) was applied. To assess the effect of genetic variation on gene expression, gender and age were included as known covariates in a linear model. All eQTL mapping was done using Matrix-eQTL<sup>61</sup>.

### Genome-wide case-control association analysis with susceptibility to candidaemia

The associations between the genetic variants and candidaemia susceptibility were described in *chapter 3*. Briefly, associations were tested by Fisher's exact test using PLINK 1.9 ([www.cog-genomics.org/plink/1.9/](http://www.cog-genomics.org/plink/1.9/))<sup>66</sup>. The genomic inflation factor ( $\lambda = 1$ ) indicated that there was no population stratification effect (Figure S11B). A P value significance threshold of  $< 5 \times 10^{-8}$  was set to call genome-wide significant associations.

### Within-case QTL mapping and survival analysis

To determine genetic variants that are associated with survival, we performed a within-case QTL mapping on a genome-wide scale using 65 candidaemia patients for which mortality dates were recorded (non-survivors). In detail, 31 patients passed away within 14 days, 18 passed away between 14 and 30 days and 16 passed away between 30 and 90 days. Multidimensional scaling analysis (MDS) of candidaemia cohort, including non-survivors, showed genetic homogeneity between non-survivors (Figure S11A). For QTL mapping, we assigned the actual day of survival as quantitative trait using PLINKv1.09<sup>55</sup>. Gender was included as known covariate in a linear model to map QTLs that influence patient survival. Regional

association plots of loci associated with survival were prepared using a web-based plotting tool, LocusZoom<sup>67</sup>. Lastly, survival analysis was done using a cohort of 148 candidaemia patients, of which 65 were non-survivors and 83 survivors. We stratified the 65 non-survivors and 83 survivors based on the SNP genotype and evaluated differences between SNP genotype strata by using a log-rank test of the R package survival. Gender was included as covariate in the survival analysis. Visualization was done with the R package survminer.

### **Within-case genome-wide association testing for patient survival**

To identify genetic variants that are associated with 14-, 30-, and 90-day survival, we run a within-case genome-wide association analysis using a survival cohort of 148 candidaemia patients. To test for association (1) with 14-day survival, we used 31 non-survivors that passed away within 14 days and 83 survivors, with (2) 30-day survival, we used 49 non-survivors that passed away within 30 days and 83 survivors, and with (3) 90-day survival, we used 65 non-survivors that passed away within 90 days and 83 survivors. Gender and the first two principal components calculated in MDS analysis (Figure S11A) were included as covariates in an additive model using SNPTEST v.2.5.4-beta3<sup>52,68,69</sup>.

### **Enrichment analysis of pQTLs for genetic variants associated with candidaemia susceptibility and patient survival**

We first called pQTLs at four different thresholds ( $5 \times 10^{-4}$ ,  $5 \times 10^{-5}$ ,  $5 \times 10^{-6}$ , and  $5 \times 10^{-7}$ ). Next, we intersected the pQTLs with variants associated with candidaemia susceptibility, and those associated with survival (identified by quantitative analysis). We then extracted P values of association with susceptibility and survival for the pQTLs binned at the four different thresholds. All graphs were visualized using the R package ggplot2.

### **Extraction of SNPs associated with infectious diseases**

SNPs associated with a number of infectious diseases that showed  $P < 1 \times 10^{-6}$  were extracted using the GWAS catalogue (<https://www.genome.gov/gwastudies/>). We selected diseases that were studied in European populations, and for which at least ten independent associations were reported per study. We then intersected the SNPs associated with infectious diseases and their proxies ( $r^2 \geq 0.8$ ) with pQTLs that showed  $P < 0.001$  in this study.

### **Acknowledgments**

The authors thank all volunteers from the 500 Functional Genomics cohort (500FG) of the Human Functional Genomics Project and Lifelines (DEEP) cohort for participation in the study. The authors would like to thank K. McIntyre

for editing the final text. # Supplementary Information

**Figure S1:** Protein expression of inflammatory proteins in plasma of candidaemia patients compared to plasma from healthy individuals (Lifelines cohort). P values were calculated using Wilcoxon rank sum test, and  $P < 0.05$  was considered to be the threshold for significance.

**Figure S2:** Unsupervised clustering of inflammatory responses in patients and healthy controls from Lifelines cohort revealed distinct clustering patterns among plasma proteins between patient and control samples. Unsupervised hierarchical clustering was performed using the measurements of 64 proteins that were expressed in both plasma of patients and healthy controls. These proteins were measured in at least 90% of the plasma samples in candidaemia patients and healthy individuals.

**Figure S3:** Protein expression of inflammatory proteins that were detected in at least 90% of the supernatants of PBMC samples stimulated with *C. albicans* yeast compared to samples stimulated with RPMI medium. P values were calculated using Wilcoxon rank sum test, and  $P < 0.05$  was considered to be the threshold for significance. Samples were stimulated with *C. albicans* yeast or RPMI medium for 24 hours, as described in Material and Methods section.

**Figure S4:** Unsupervised clustering of inflammatory proteins profiled in *Candida*-stimulated PBMCs and patients showed different clustering patterns between these two groups, suggesting that additional factors in plasma of patients contribute to inflammatory responses in patients. Proteins were detected in at least 90% of the samples and were expressed in both patients and PBMC samples ( $N_{\text{proteins}} = 30$ ).

**Figure S5:** Minimal effect of cell counts and non-genetic host factors on inflammatory proteins in response to *C. albicans*. (A) Cell counts weakly influence the levels of inflammatory proteins in PBMCs stimulated with *C. albicans* yeast for 24 hours. Unsupervised hierarchical clustering was performed using Spearman correlation as the measure of similarity. The red color depicts the strong positive correlation whereas blue color indicates the strong negative correlation. (B) Correlations of age, gender, oral contraceptive use and BMI to protein production released from PBMCs upon stimulation with *C. albicans* yeast. Significance of non-genetic factors (x axis) in relation to different proteins (y axis) is shown. P values have been FDR-corrected. Blue indicates a significant positive correlation (P value < 0.05). All significantly correlated proteins with age or gender showed a positive (pos) correlation.

**Figure S6:** Density plots of the distribution of inflammatory proteins released from PBMCs stimulated with *C. albicans* yeast isolated from healthy individuals of 500FG cohort. Majority of proteins follows non-normal distribution after log2 transformation, with the exception of three proteins, CD40, VEGF-A and TNFRSF9. Related to Table S3.

**Figure S7:** Density plots of the distribution of inflammatory proteins released from PBMCs stimulated with *C. albicans* yeast isolated from healthy individuals of Lifelines cohort. Majority of proteins follows non-normal distribution after log2 transformation. Related to Table S7.

**Figure S8:** Box plots showing the association of genotypes from genome-wide significant pQTLs identified in the joint analysis between the 500FG and Lifelines DEEP cohorts with *Candida*-induced protein levels. Boxplot of (A) SNP rs2501301 with CCL4 levels, (B) SNP rs1398749 with MCP-1 levels, (C) SNP rs358011 with VEGF-A levels, (D) SNP rs392422 with IL-8 levels, (E) SNP rs1699130 with IL-8 levels, (F) SNP rs2488633 with IL-8, (G) SNP rs1572285 with MCP-2, (H) SNP rs247426 with MCP-3, (I) SNP rs247426 with CXCL9, and (J) rs34774255 with CXCL9 levels. The numbers of individuals per genotype are shown in parentheses below each box plot. P values were obtained using Wilcoxon Rank-Sum test to compare if there are statistically significant differences of protein levels between SNP genotypes.  $P < 0.05$  was considered to be the threshold of significance. Related to Table 1.

**Figure S9:** Pathway enrichment analysis of *Candida*-induced pQTLs with a P value <  $9.99 \times 10^{-4}$  showed an over-representation of genes involved in hemostasis and metabolism of lipids and lipoproteins based on Reactome database. x axis shows the enrichment p-values for each pathway.

**Figure S10:** Heatmap shows all genome-wide significant pQTLs that have at least two associations with distinct proteins at P threshold  $1.56 \times 10^{-4}$  when correcting for multiple testing. All associations show the same allelic direction in both 500FG and Lifelines DEEP cohorts ( $P_{\text{heterogeneity}} \geq 0.05$ ). Associations with P value above this cut-off are set zero for visualization purposes. For clustering, we used an unsupervised clustering approach based on the negative log<sub>10</sub> of the P values. Color scale indicates the direction of effect, with red showing a positive z score value and blue showing a negative z score value. Related to Fig. 4.

**Figure S11:** (A) Multidimensional scaling analysis (MDS) to check for population stratification in the candidaemia cohort consisted of 178 cases. Out of 178 cases, 65 were non-survivors and 83 survivors. We do not have available mortality data for the rest of cases. Dimensions were calculated on the basis of the identity-by-descent (IBD) pairwise distance among all patients and the first-dimension values were plotted against the second-dimension values. Non-survivors (n = 65), survivors (n = 83) and the rest of candidaemia cases are highlighted in different colors. (B) Quantile-quantile (QQ) plot of  $\log_{10}$  (P values) of primary GWAS P-values to those expected for a null distribution. The genetic inflation factor  $\lambda$  for all SNPs was 1, indicating no population stratification.

**Figure S12:** A positive Spearman correlation coefficient was observed between protein concentrations of IL-6 in log2 picogram/ml measured with ELISA and NPX values as measured with OLINK technology.

**Table S1.** Inflammatory proteins measured with high-throughput OLINK technology in plasma samples of candidaemia patients. Out of 92 proteins measured, 64 were detected in at least 90% of the samples.

**Table S3.** Inflammatory proteins measured with high-throughput OLINK technology in supernatants of PBMCs isolated from individuals of 500FG cohort. We used proteins that were detected in at least 90% of the samples for further analysis. Shapiro test was used to test for normality under the null hypothesis that the protein distribution is normal. If P value < 0.05, the distribution is non-normal. Most proteins follow non-normal distribution. Chr: chromosome

**Table S7.** Inflammatory proteins measured with high-throughput OLINK technology in *Candida*-stimulated supernatants of PBMCs isolated from individuals of Lifelines DEEP cohort. We used proteins that were detected in at least 90% of the samples for further analysis. Shapiro test was used to test for normality under the null hypothesis that the protein distribution is normal. If  $P$  value  $< 0.05$ , the distribution is non-normal. Most proteins follow non-normal distribution. Chr: chromosome.

**Table S8.** The genome-wide significant pQTLs identified in the joint analysis show at least two associations with distinct proteins at  $P < 0.05/(10 \times 32) = 1.56E-04$ , indicating potential pleiotropy between genome-wide significant pQTLs and measured inflammatory proteins. The cutoff reflects a conservative approach to multiple testing for all identified genome-wide significant pQTLs (10) with all tested proteins (32). Only associations at  $P < 1.56E-04$  with the same allelic direction between 500FG and Lifelines DEEP cohort are shown in the table. SNP rs2488633 showed a single association at  $P$  threshold of  $1.56E-04$  and it was therefore excluded from the analysis of pleiotropic effects of genome-wide significant pQTLs on proteins. Chr: chromosome; HetPVal: P value of heterogeneity between 500FG and Lifelines DEEP cohort; Direction column shows the allelic direction between 500FG and Lifelines DEEP cohort.

# The MHC locus and genetic susceptibility to autoimmune and infectious diseases

Vasiliki Matzaraki<sup>1</sup> , Vinod Kumar<sup>1</sup>, Cisca Wijmenga<sup>1,2\*</sup> and Alexandra Zhernakova<sup>1</sup>**Abstract**

In the past 50 years, variants in the major histocompatibility complex (MHC) locus, also known as the human leukocyte antigen (HLA), have been reported as major risk factors for complex diseases. Recent advances, including large genetic screens, imputation, and analyses of non-additive and epistatic effects, have contributed to a better understanding of the shared and specific roles of MHC variants in different diseases. We review these advances and discuss the relationships between MHC variants involved in autoimmune and infectious diseases. Further work in this area will help to distinguish between alternative hypotheses for the role of pathogen in autoimmune disease development.

**Introduction**

The major histocompatibility complex (MHC) locus, also known as the human leukocyte antigen (HLA) locus, spans around 4 Mbp on the short arm of chromosome 6 (6p21.3; Box 1). Molecules encoded by this region are involved in antigen presentation, inflammation regulation, the complement system, and the innate and adaptive immune responses, indicating the MHC's importance in immune-mediated, autoimmune, and infectious diseases [1]. Over the past 50 years, polymorphisms in the MHC locus have been shown to influence many critical biological traits and individuals' susceptibility to complex, autoimmune, and infectious diseases (Boxes 2 and 3). In addition to autoimmune and inflammatory diseases, the MHC has recently been found to play a role in some neurological disorders [2–6], implicating autoimmune components in these diseases.

The genetic structure of the MHC is characterized by high levels of linkage disequilibrium (LD) compared to the rest of the genome, which means there are technical challenges in identifying MHC single nucleotide polymorphisms (SNPs), alleles, and amino acids. However, the recent availability of dense genotyping platforms, such as the custom-made Illumina Infinium SNP chip (ImmunoChip) [7], and of MHC reference panels has helped to fine-map the locus, improving our understanding of its disease associations and our ability to identify functional variants.

In this review, we discuss recent advances in mapping susceptibility variants in the MHC, using autoimmune and infectious diseases as examples (Boxes 2 and 3). We also discuss the relationships between the MHC variants involved in both autoimmune and infectious diseases and offer insights into the MHC-associated immune responses underlying disease onset and pathogenesis. Finally, we discuss future directions for studying genetic variation in the MHC and how learning about the variation at this locus will aid understanding of disease pathogenesis.

**Advances in mapping susceptibility variants in the MHC locus**

Several computational and empirical challenges complicate the mapping of MHC susceptibility variants. One fundamental challenge is that the MHC has many sequence and structural variations [8], which differ between populations and complicate haplotype inference. Another is that high and extensive LD in the locus makes it difficult to identify causal and independent loci. Non-additive allelic effects in the MHC, and epistatic effects between the MHC and other loci, can also complicate inference of the underlying haplotype structure and disease susceptibility variants.

In recent years, large volumes of sequencing data have made it possible to impute MHC variation on a wide scale, thereby improving our understanding of variability at this locus and of the haplotype structures and

**Box 1. The major histocompatibility complex locus**

The major histocompatibility complex (MHC) was discovered in the mouse in 1936 [128]. It covers 0.13% of the human genome [1] and shows a high degree of polymorphism and extensive patterns of linkage disequilibrium (LD), which differ among populations. The large number of MHC alleles means each individual has a nearly unique set of peptide-presenting allotypic MHC molecules, and each MHC allotype confers the ability to bind different peptides. The MHC genes are classified into five subregions from the telomeric to the centromeric end: the extended class I, class I, class III, class II, and the extended class II regions [1]. The extended MHC region contains more than 400 annotated genes and pseudogenes that extend beyond the boundaries defining the MHC.

The class I region includes the three classic human leukocyte antigen (HLA) gene loci: HLA-A, HLA-B, and HLA-C; three non-classic HLA-E, HLA-F, and HLA-G gene loci, which show limited polymorphism compared to the classic class I loci; and other related non-coding genes and pseudogenes [1]. The main function of HLA class I molecules, which are expressed in all nucleated cells, is to present non-self antigens derived from intracellular sources, such as viruses, to CD8<sup>+</sup> T cells (cytotoxic T cells), which then kill the antigen-presenting cells (APCs) [129]. CD8<sup>+</sup> T cells interact with the cognate peptide-MHC I complexes via their T-cell receptor (TCR) and co-receptor molecule CD8.

The class II region includes the classic gene loci HLA-DP, HLA-DQ, and HLA-DR and also the non-classic HLA-DO and HLA-DM loci [1]. The classic genes are expressed on the surface of professional APCs, which take up antigens derived from extracellular sources [130], such as bacteria or food, and present them to CD4<sup>+</sup> T helper cells. This leads to the secretion of various small proteins, including cytokines, which regulate other immune cells such as macrophages or B cells. In turn, macrophages can destroy ingested microbes, and activated B cells can secrete antibodies. CD4<sup>+</sup> T cells interact with the cognate peptide-MHC II complexes via their TCR and the co-receptor molecule CD4. Non-classic molecules are exposed in internal membranes in lysosomes, which help load antigenic peptides on to classic MHC class II molecules.

The class III region contains genes involved in inflammation, for example, complement cascades (C2, C4, CFB), and in cytokine production (TNF, LTA, LTB), as well as many other genes of non-immune or unknown function that may not be involved in inflammation [1].

Overall, classic MHC I and II molecules present peptides for T-cell surveillance and are, therefore, critical for priming the cellular adaptive immune responses.

enabling reference panels to be created. The availability of accurate reference panels and a large number of genotyped individuals has allowed the identification of independent variants and improved our understanding of their contribution to disease heritability and pathways underlying disease biology [9, 10].

**Advances in laboratory-based mapping of MHC variation**

Increased throughput, accuracy, and read length in next-generation sequencing (NGS) technologies, as well as the development of user-friendly bioinformatics tools, have enabled higher resolution MHC typing [11]. For instance, whole-genome sequencing (WGS) was successfully used to type HLA-A alleles at full resolution in 1070 healthy Japanese individuals [12] and to fully evaluate HLA-E variability in West African populations [13]. However, the main problem with MHC sequencing using current technologies is the relatively short read lengths, which limit the amount of allelic data that can be generated at a high resolution. Long-range PCR amplification approaches, such as the use of PacBio systems for single molecule real-time sequencing, significantly increase read-length and the resolution for typing MHC alleles [14]. In a comparison of MHC typing in an Indian population using sequence-specific primers, NGS (Roche/454) and single molecule sequencing (PacBio RS II) platforms, higher resolution typing was achieved for MHC class I (HLA-A, HLA-B, and HLA-C) and class II genes (HLA-DRB1 and HLA-DQB1) using the PacBio platform, with a median read length of 2780 nucleotides [15].

High-density SNP panels, such as the Immunochip platform [7], which has been widely implemented in immunogenetics studies, are a cheaper, faster, and easier alternative to genotyping than direct MHC typing and NGS methods. The Immunochip contains a dense panel of SNPs from the MHC locus, which enables missing classic MHC variants to be inferred in silico, where the imputation is based on the haplotype structure present in large reference panels (Fig. 1). This fine-mapping approach has been used for several autoimmune and inflammatory diseases (Table 1) and for a few infectious diseases (Additional file 1), thereby allowing comprehensive interrogation of the MHC. Moreover, population-specific reference panels made by deep sequencing and used to impute genotypes allow identification of very rare variants and novel single-nucleotide variants in the human genome. This is illustrated by a recent study in which the authors first built a Han Chinese MHC-specific database by deep sequencing the region in 9946 patients with psoriasis and 10,689 healthy controls, and then used this reference panel to impute genotype data to fine-map psoriasis-associated variants [16]. Notably, functional variants in non-coding regions can be

## Box 2. Clinical characteristics and prevalence of autoimmune diseases in Europeans

### Rheumatoid arthritis

Chronic inflammation of synovial joints, with a prevalence of 0.5–1%. In some individuals, rheumatoid arthritis can damage a wide variety of body systems, including the skin, eyes, lungs, heart, and blood vessels.

### Celiac disease

Chronic inflammation of the intestine triggered by gluten peptides in the diet and leading to flattening of the mucosa. Prevalence is 0.5–2%.

### Psoriasis

An inflammatory skin condition characterized by rapid growth and skin cell reproduction. The disease trigger is unknown. The prevalence is 0.5–1% worldwide, but it is higher (2%) in Europeans.

### Ankylosing spondylitis

A chronic, degenerative, and inflammatory form of arthritis, primarily affecting the spine and sacroiliac joints, and eventually leading to spinal fusion. This makes the spine less flexible and can result in a hunchback posture. It has a prevalence of 0.025%.

### Systemic lupus erythematosus

Chronic inflammation that can affect any part of the body, although it often attacks the heart, joints, skin, lungs, blood vessels, liver, kidneys, and nervous system. It has a prevalence of 0.04–0.12%.

### Type 1 diabetes

Characterized by the destruction of pancreatic beta-cells, leading to insufficient release of insulin from the pancreas. It has a prevalence of 0.2–0.3%.

### Multiple sclerosis

Characterized by autoimmune attack on the central nervous system, leading to demyelination of neurons, and potentially debilitating physical and mental symptoms. It has a prevalence of 0.02%.

### Graves' disease

An autoimmune thyroid disorder leading to the overproduction of thyroid hormones (hyperthyroidism). Graves' disease occurs in about 0.5% of males and 3% of females [131]. It is the most common cause of hyperthyroidism in the USA, affecting about 1 in 200 people (0.5%) according to the National Institutes of Health (<https://ghr.nlm.nih.gov/condition/graves-disease#statistics>).

### Inflammatory bowel disease

A group of intestinal disorders involving chronic inflammation of the digestive tract. The two most common types of inflammatory bowel disease are Crohn's disease (CD), which is

characterized by inflammation of any part of the digestive tract, and ulcerative colitis (UC), in which the inflammation is mostly localized in the large intestine. In Europe, CD has a prevalence varying from 0.00015 to 0.2%, whereas the prevalence of UC varies from 0.0024 to 0.3% [132].

### Dermatomyositis

A rare idiopathic myopathy characterized by inflammation, primarily of the muscles and skin. It may also affect the joints, esophagus, lungs, and heart. The disease incidence ranges from 1.2 to 17 new cases per 1,000,000 inhabitants, with a prevalence between 0.005 and 0.011% [133].

identified, as shown in a Japanese cohort of 1070 healthy individuals [12]. These variants would be impossible to discover using SNP microarrays or low coverage sequencing on the same sample size (Fig. 1, Table 1).

MHC associations revealed by genome-wide association studies (GWAS) can often not be fine-mapped to a single allele at a single locus; rather they comprise independent effects from multiple loci (see “Role of MHC variants in human diseases”). The presence of these multiple, independent effects highlights the heterogeneous nature within and between diseases, which may lead to varying immunological responses. Fine-mapping has also shown that autoimmune diseases share MHC alleles and hence molecular pathways, which are likely to represent targets for shared therapies. For instance, the major associations within MHC class II across autoimmune diseases imply that modulating T-cell receptor (TCR) activation by using peptide-bearing MHC molecules on antigen-presenting cells (APCs) could be therapeutically useful [17]. Shared MHC genetic factors have also been observed between autoimmune and infectious diseases, suggesting that human genetic architecture has evolved in response to natural selection as determined by various infectious pathogens [18].

## Advances in computational approaches for mapping MHC variation

Long-range LD between loci and SNP markers across the MHC offers an alternative approach to interrogate functional MHC variation through imputation. The development of different imputation tools using population-specific reference panels has enhanced the interpretation of genotype data derived from genome-wide platforms. MHC imputation is done using reference panels containing both genetic information and classic HLA serotyping, thus allowing identification of MHC allelic and amino acid variants. It is advantageous to impute allele and amino acid variants in the MHC because background sequence diversity causes the binary SNP concept to fail, technically speaking, while

**Box 3. Infectious diseases and infection-related GWAS phenotypes****HIV infection**

Infection by the lentiviral human immunodeficiency virus (HIV; a subgroup of retrovirus) is a global public health issue. According to the World Health Organization (WHO), 36.7 million people were living with HIV at the end of 2015 (<http://www.who.int/>). The virus attacks human immune cells. Over time, HIV infection develops into acquired immunodeficiency syndrome (AIDS), a condition characterized in humans by progressive loss of immune function and leading to life-threatening opportunistic infections and cancers.

**Dengue shock syndrome**

Dengue shock syndrome is the most dangerous and severe complication of infection with the dengue virus. It is characterized by increased vascular permeability, together with myocardial dysfunction and dehydration. Dengue virus is a single, positive-stranded RNA virus of the *Flaviviridae* family; it is mainly transmitted by mosquitos. Dengue is found in tropical and sub-tropical climates, mostly in urban and semi-urban regions. The WHO estimates that about half of the world's population is now at risk.

**Hepatitis B virus infection**

Hepatitis B virus (HBV) is a double-stranded DNA virus belonging to the *Headnaviridae* family. The virus can cause both acute and chronic infections. Chronic infection with HBV leads to serious liver disease, often progressing to liver cirrhosis and hepatocellular carcinoma [134]. The WHO estimates that about 240 million people live with chronic HBV infection worldwide, with the highest prevalence seen in Africa and Asia.

**Hepatitis C virus infection**

Hepatitis C virus (HCV) is a single-stranded RNA virus of the *Flaviviridae* family. It has the same target as HBV—the liver—and can cause both acute and chronic infections. The WHO estimates that 130–150 million people worldwide have chronic infection; many of these will go on to develop liver cirrhosis or liver cancer. The prevalence of HCV infections is highest in Africa and Central and East Asia.

**Human papillomavirus virus infection**

Human papillomavirus virus (HPV) covers a highly diverse group of DNA papillomaviruses that are common worldwide. They can infect either mucosal or cutaneous epithelia but, in most cases, can be cleared by the human immune system. If infection persists, certain high-risk mucosal types (e.g., HPV16 and HPV18) can lead to cervical cancer and other anogenital and oropharyngeal cancers.

**Leprosy**

Leprosy is a chronic infectious disease caused by *Mycobacterium leprae*; it mainly affects the skin, peripheral nerves, mucosa of the upper respiratory tract, and eyes. It is curable using multidrug therapy, which the WHO has made available free of charge to patients worldwide since 1995. The WHO reports on leprosy in 121 countries and territories, but not in Europe, and gave a prevalence of 175,554 cases at the end of 2014. Thus, leprosy remains a serious public health problem, especially in developing countries. Leprosy is classified into five distinct clinical subtypes. At one end of the spectrum, tuberculoid leprosy (TT) is characterized by fewer lesions and resistance to mycobacteria proliferation, caused by a robust Th1 antigen-specific cellular response. In contrast, at the other end of the spectrum, lepromatous leprosy (LL) is characterized by numerous lesions and proliferation of mycobacteria because of a weak or absent cellular immune response and a dominant Th2 response. Between TT and LL, there is a range of intermediate forms and manifestations [135].

**Tuberculosis**

Tuberculosis is caused by *Mycobacterium tuberculosis*; it most often affects the lungs but can affect other parts of the body. It is one of the top infectious killers worldwide, with over 95% of cases and deaths occurring in developing countries. Sub-Saharan Africa has the highest disease prevalence. Pulmonary tuberculosis is the only transmissible form of the disease and the most common form seen in all ages (WHO, Global Tuberculosis Report 2016; <http://apps.who.int/iris/bitstream/10665/250441/1/9789241565394-eng.pdf?ua=1>). In 2015, the WHO estimated 10.4 million new (incident) tuberculosis cases worldwide.

**Leishmaniasis**

Leishmaniasis is caused by the protozoan *Leishmania* parasites, which are transmitted to humans by infected female sandfly bites. The disease has three forms: visceral (also known as kala-azar, the most serious form of the disease), cutaneous (the most common), and mucocutaneous. It is classified as a neglected tropical disease, and the WHO estimates that there are 900,000 to 1.3 million new cases and 20,000 to 30,000 deaths annually. Visceral leishmaniasis is endemic in the Indian subcontinent and in East Africa, while cutaneous leishmaniasis is most common in the Americas, the Mediterranean basin, the Middle East, and Central Asia. Cases of mucocutaneous leishmaniasis occur in South America (Bolivia, Peru, and Brazil; WHO Fact Sheet, updated September 2016; (<http://www.who.int/mediacentre/factsheets/fs375/en/>)).

many SNPs have more than two alleles and various amino acids can be contained in the same position. For instance, six possible amino acid variants at position 11 in the HLA-DRB1 gene show the strongest association to rheumatoid arthritis (RA) [19]. Two of these (valine and leucine) confer susceptibility to RA, whereas the other four (asparagine, proline, glycine and serine) are protective.

Several tools allowing imputation of classic HLA alleles at four-digit resolution are now available for MHC imputation analysis; the most common are SNP2HLA [20], HLA\*IMP:01 [21], and an improved HLA\*IMP:02 [22]. HLA\*IMP:02 outperforms HLA\*IMP:01 on heterogeneous European populations and it increases the power and accuracy in cross-European GWAS [22]. Missing data are also better tolerated in HLA\*IMP:02, while SNP genotyping platforms must be selected in HLA\*IMP:01 [21, 22]. SNP2HLA not only imputes classic alleles but also amino acids by using two European reference panels, one based on data from HapMap-CEPH (90 individuals), and the other on the Type 1 Diabetes Genetics Consortium (T1DGC) study [20]. Another tool, HLA-VBSeq, allows imputation of MHC alleles at full resolution from whole-genome sequence data [23]. HLA-VBSeq does not require prior knowledge of MHC allele frequencies and can therefore be used for samples from genetically diverse populations [23]. It has successfully typed HLA-A alleles at full resolution in a Japanese population and identified rare causal variants implicated in complex human diseases [12].

One commonly used European reference panel for imputation is the T1DGC panel, which covers SNP genotyping and classic HLA serotyping information for 5225 unrelated individuals [20]. Similar population-specific reference panels have been developed for non-European

studies to investigate the risk of psoriasis in Chinese populations [16] and of Graves' disease and RA in Japanese populations. The panels have also been used to impute MHC alleles and amino acids for East Asian and Korean populations [24–26].

Using a single reference genome for regions like the MHC, which has substantial sequence and structural diversity, results in poor characterization. To counteract this, an algorithm was developed to infer much of the variation in the MHC; it allows genome inference from high-throughput sequencing data using known variation represented in a population reference graph (PRG) [27]. Specifically, the PRG constructed for the MHC combined eight assembled haplotypes, the sequences of known classic HLA alleles, and 87,640 SNP variants from the 1000 Genomes Project [28]. This approach is considered to be an intermediate step between de novo assembly and mapping to a single reference, but requires careful attention to the variation included in the PRG [27].

Despite the development of new tools to investigate MHC variation, the robustness of imputation depends largely on the reference panel and SNP selection. The frequency of alleles can differ between populations, thus highlighting the need to use population-specific reference panels to impute MHC alleles and amino acids. Additionally, the use of many samples is possible for analyzing the non-additive effects of MHC alleles on a wide scale, as described by Lenz et al. for celiac disease (CeD), psoriasis, and type 1 diabetes (T1D) [29]. These non-additive effects could explain our inability to identify susceptibility variants. However, one important limitation of existing imputation methods is that they are limited to the classic MHC alleles and their amino acids. Another limitation is that accuracy is lower for low frequency or rare variants [20, 30]; this can be improved by increasing the reference panel size, together with the use of deep sequencing data. Ascertainment bias and lower LD also make it challenging to impute MHC variants in some non-European populations, such as Africans.

MHC genetic variation mediates susceptibility to a wide range of complex diseases, including infectious and autoimmune diseases. The large volume of data generated by recent GWAS has provided an excellent opportunity to apply imputation tools used to fine-map MHC associations to classic alleles and amino acids, as described below for autoimmune diseases. Overall, MHC imputation has proved to be a robust and cost-effective way to identify causal genes underlying disease pathogenesis. Ultimately, knowing the causal genes will help explain disease heritability and lead to a better understanding of the molecular pathways involved in disease pathogenesis. Such work helps to pinpoint potential therapeutic targets.

**Table 1** Major histocompatibility complex (MHC) associations to autoimmune diseases, as described by fine-mapping studies

Disease	Classic associated locus	Fine-mapping: top locus	HLA class for top association	Fine-mapping: independent associations at $P < 5 \times 10^{-8}$	HLA class for independent association	Population	Sample size	Reference
RA	Shared epitope (HLA-DRB1 AA70-74)	HLA-DRB1: AA 11, 13, 71, 74	II	HLA-B AA 9	I	European	5018 individuals with seropositive RA, 14,974 unaffected controls	[19]
		HLA-DRB1: AA 11, 57, 74	II	HLA-DPB1 AA 9	II	Chinese, Korean	2782 seropositive RA cases, 4315 controls	[34]

### Role of MHC variants in human diseases

#### Insights into MHC susceptibility for autoimmune diseases: fine-mapping results, epistasis, and disease biology

Associations between the MHC and autoimmune diseases reported in the 1970s were some of the earliest described genetic associations [31, 32], and they remain the strongest risk factors for autoimmune diseases. After the development of wide-screen genotyping platforms and imputation pipelines, MHC imputation and fine-mapping were performed in European and Asian populations for most common autoimmune diseases, including RA [19, 25, 33, 34], CeD [35], psoriasis [36], ankylosing spondylitis (AS) [37], systemic lupus erythematosus (SLE) [33, 38–41], T1D [42, 43], multiple sclerosis (MS) [44, 45], Graves' disease [24], inflammatory bowel disease (IBD) [46], and dermatomyositis (DM) [47]. Table 1 shows the main associated variants and independently associated loci for autoimmune diseases.

In 2012, a pioneering MHC fine-mapping study, performed in individuals of European ancestry with RA [19], confirmed the strongest association with the class II HLA-DRB1 gene, as well as other independent associations. Previously an increased risk of RA was reported for a set of consensus amino acid sequences at positions 70–74 in the HLA-DRB1 gene, known as the “shared epitope” locus [48]. The imputed data revealed the most significant associations were with two amino acids at position 11, located in a peptide-binding groove of the HLA-DR heterodimer. This suggested a functional role for this amino acid in binding the RA-triggering antigen. Similar fine-mapping studies followed for other autoimmune diseases (Table 1).

In general, in most autoimmune diseases, fine-mapping strategies have confirmed the main associated locus reported by serotype analysis within a certain MHC locus. Such strategies have also allowed identification of specific allelic variants or amino acids, as well as independent variants in different HLA classes. For instance, in CeD, the strongest association was with the known DQ-DR locus, and five other independent signals in classes I and II were also identified. CeD is the only autoimmune disease for which the antigen, gluten, is known and well studied. Gluten is a dietary product in wheat, barley, and rye. It is digested in the intestine and deamidated by tissue transglutaminase enzymes such that it perfectly fits the binding pockets of a particular CeD-risk DQ heterodimer (encoded by the DQ2.2, DQ2.5, and DQ8 haplotypes). This association was confirmed by MHC fine-mapping, which indicated roles for four amino acids in the DQ genes with the strongest independent associations to CeD risk [35]. Similarly, the main associations were determined for T1D, MS, and SLE within the MHC class II locus (the associations for these three diseases are to a particular HLA-DQ-DR

haplotype), and there are also independent, but weaker associations with the class I and/or III regions. In DM, fine mapping in an Asian population identified MHC associations driven by variants located around the MHC class II region, with HLA-DP1\*17 being the most significant [47]. In contrast, the primary and strongest associations in psoriasis and AS were to MHC class I molecules, while independent associations to the class I locus were also reported for IBD and Graves' disease. Class III variants are weakly implicated in autoimmune diseases, but several associations in the MHC class III region were seen for MS; for instance, the association to rs2516489 belonging to the long haplotype between *MICB* and *LST1* genes. The association signal to rs419788-T in the class III region gene *SKIV2L* has also been implicated in SLE susceptibility, representing a novel locus identified by fine-mapping in UK parent-child trios [39]. An independent association signal to class III was also identified (rs8192591) by a large meta-analysis of European SLE cases and controls and, specifically, upstream of *NOTCH4* [40]. However, further studies are needed to explain how these genetic variations contribute to predisposition to SLE.

In addition to identifying independent variants, MHC fine-mapping studies permit analysis of epistatic and non-additive effects in the locus. These phenomena occur when the effect of one allele on disease manifestation depends on the genotype of another allele in the locus (non-additive effect), or on the genotype of the “modifier” gene in another locus (epistasis). Non-additive MHC effects were established in CeD, in which knowing gluten was the causal antigen offered an advantage in investigating the antigen-specific structure of the DQ-heterodimer. CeD risk is mediated by the presence of several HLA-DQ haplotypes, including the DQ2.5, DQ2.2, and DQ8 haplotypes, which form the specific pocket that efficiently presents gluten to T cells. These haplotypes can be encoded either in *cis*, when both DQA1 and DQB1 are located on the same chromosome, or in *trans*, when they are located on different chromosomes. Some DQ allelic variants confer susceptibility to CeD only in combination with certain other haplotypes, forming a CeD-predisposing *trans*-combination. For example, HLA-DQA1\*0505-DQB1\*0301 (DQ7) confers risk to CeD only if it is combined with DQ2.2 or DQ2.5, contributing to the formation of susceptible haplotypes in *trans*. In particular, DQ7/DQ2.2 heterozygosity confers a higher risk for CeD than homozygosity for either of these alleles, and is an example of a non-additive effect for both alleles.

Unlike CeD, the exact haplotypes and their associated properties remain unknown for most other autoimmune diseases; therefore, analyzing non-additive effects might yield new insights into potentially disease-causing

antigens. Lenz et al. provided evidence of significant non-additive effects for autoimmune diseases, including CeD, RA, T1D, and psoriasis, which were explained by interactions between certain classic HLA alleles [29]. For instance, specific interactions that increase T1D disease risk were described between HLA-DRB1\*03:01-DQB1\*02:01/DRB1\*04:01-DQB1\*03:02 genotypes [49] and for several combinations of the common HLA-DRB1, HLA-DQA1, and HLA-DQB1 haplotypes [43]. In AS, epistatic interaction was observed for combinations of HLA-B\*27 and HLA-B\*60, indicating that individuals with the HLA-B\*27+/HLA-B\*60+ genotype have a high risk of developing AS [50]. Moreover, a recent study in MS found evidence for two interactions involving class II alleles: HLA-DQA1\*01:01-HLA-DRB1\*15:01 and HLA-DQB1\*03:01-HLA-DQB1\*03:02, although their contribution to the missing heritability in MS was minor [44].

Epistatic interactions between MHC and non-MHC alleles have also been reported in several autoimmune diseases, including SLE, MS, AS, and psoriasis. For instance, in a large European cohort of SLE patients, the most significant epistatic interaction was identified between the MHC region and cytotoxic T lymphocyte antigen 4 (*CTLA4*) [9], which is upregulated in T cells upon encountering APCs. This highlights that appropriate antigen presentation and T-cell activation are important in SLE pathogenesis [9]. Notably, interactions between MHC class I and specific killer immunoglobulin receptor (KIR) genes are important in predisposition to autoimmune diseases such as psoriatic arthritis, scleroderma, sarcoidosis, and T1D [51–54]. KIR genes are encoded by the leukocyte receptor complex on chromosome 19q13 and expressed on natural killer cells and subpopulations of T cells [55]. Finally, epistatic interactions between MHC class I and *ERAP1* have been described for AS, psoriasis, and Behçet's disease [10].

Association of novel MHC variants and identification of interaction effects within the MHC are increasing our understanding of the biology underlying autoimmune and inflammatory diseases. Fine-mapping the main associated locus within HLA-DQ-DR haplotypes has allowed determination of the key amino acid positions in the DQ or DR heterodimer. Pinpointing specific amino acids leads to a better understanding of the structure and nature of potential antigens for autoimmune or inflammatory diseases, and these can then be tested through binding assays and molecular modeling. The fact that these positions are located in peptide-binding grooves suggests they have a functional impact on antigenic peptide presentation to T cells, either during early thymic development or during peripheral immune responses [19]. In addition, analysis of non-additive effects in MHC-associated loci offers the possibility to identify

antigen-specific binding pockets and key amino acid sequences. For example, identification of the protective, five-amino acid sequence DERAA as a key sequence in the RA-protective HLA-DRB1:13 allele, and its similarity to human and microbial peptides, led to identification of (citrullinated) vinculin and some pathogen sequences as novel RA antigens [56].

The identification of independent signals in MHC classes I and III for many autoimmune diseases implies that these diseases involve novel pathway mechanisms. For example, association of CeD to class I molecules suggests a role for innate-like intraepithelial leucocytes that are restricted to class I expression and that are important in epithelial integrity and pathogen recognition [57]. Class I associations to RA, T1D, and other autoimmune diseases suggest that CD8<sup>+</sup> cytotoxic cells are involved in disease pathogenesis, as well as CD4<sup>+</sup> helper T cells.

Discovering the epistatic effects of MHC and non-MHC loci can also shed light on disease mechanisms. For example, *ERAP1* loss-of-function variants reduce the risk of AS in individuals who are HLA-B\*27-positive and HLAB-40:01-positive, but not in carriers of other risk haplotypes [37]. Similar epistatic effects were also observed for psoriasis, such that individuals who carry variants in *ERAP1* showed an increased risk only when they also carried an HLA-C risk allele [58]. In line with these observations, mouse studies have shown that *ERAP1* determines the cleavage of related epitopes in such a way that they can be presented by the HLA-B\*27 molecule [37]. Confirming that certain epitopes must be cleaved by *ERAP1* to be efficiently presented by CD4<sup>+</sup> and CD8<sup>+</sup> cells will be a critical step in identifying specific triggers for autoimmune diseases.

The recent discoveries of genetic associations between MHC alleles and autoimmune diseases are remarkable and offer the potential to identify disease-causing antigens. This would be a major step towards developing new treatments and preventing disease. However, we still do not understand exactly how most associated alleles and haplotypes work, and extensive functional studies are needed to clarify their involvement in disease.

#### Explained heritability by independent MHC loci for autoimmune diseases

Heritability is an estimation of how much variation in a disease or phenotype can be explained by genetic variants. Estimating heritability is important for predicting diseases but, for common diseases, it is challenging and depends on methodological preferences, disease prevalence, and gene–environment interactions that differ for each phenotype [59]. It is therefore difficult to compare

heritability estimates across diseases. Nevertheless, for many diseases, estimates have been made as to how much phenotypic variance can be explained by the main locus and by independent MHC loci [29].

For autoimmune diseases with a main association signal coming from a class II locus, the reported variance explained by MHC alleles varies from 2–30% [9]. The strongest effect is reported for T1D, in which the HLA-DR and HLA-DQ haplotypes explain 29.6% of phenotypic variance; independently associated loci in HLA-A, HLA-B, and HLA-DPB1 together explain about 4% of the total phenotypic variance, while all other non-MHC loci are responsible for 9% [60]. Similarly, in CeD, which has the same main associated haplotype as T1D, the HLA-DQ-DR locus explains 23–29% of disease variance (depending on the estimated prevalence of disease, which is 1–3%), whereas other MHC alleles explain 2–3%, and non-MHC loci explain 6.5–9% [35]. In seropositive RA, 9.7% of phenotypic variance is explained by all the associated DR haplotypes, whereas a model including three amino acid positions in DRB1, together with independently associated amino acids in HLA-B and HLA-DP loci, explains 12.7% of the phenotypic variance [19]. This indicates that non-DR variants explain a proportion of heritability comparable to that in other non-MHC loci (4.7–5.5% in Asians and Europeans) [19]. The non-additive effects of DQ-DR haplotypes can also explain a substantial proportion of phenotypic variance: 1.4% (RA), 4.0% (T1D), and 4.1% (CeD) [29]. In MS, the major associated allele, DRB1\*15:01, accounts for 10% of the phenotypic variance, whereas all the alleles in DRB1 explain 11.6%. A model including all of the independent variants (and those located in classes I, II, and III) explains 14.2% of the total variance in MS susceptibility [45].

In SLE, the proportion of variance explained by the MHC is notably lower, at only 2% [41], and is mostly due to class II variants. In IBD, the association with MHC is weaker than in classic autoimmune diseases, with a lower contribution seen in Crohn's disease (CD) than in ulcerative colitis (UC) [61]. The main and secondary variants can now explain 3.1% of heritability in CD and 6.2% in UC, which is two to ten times greater than previously attributed by main effect analysis in either disease (0.3% in CD and 2.3% in UC for the main SNP effect) [46]. Among all the diseases discussed here, the main effect of the associated haplotype is far stronger than the independent effects from other loci (with the exception of IBD, in which the MHC association is weaker overall). However, independent MHC loci can now explain a comparable amount of the disease variance to that explained by the non-MHC associated genes known so far.

#### Insights into MHC susceptibility for infectious diseases: GWAS, fine-mapping results, and epistasis

In principle, an infectious disease is caused by interactions between a pathogen, the environment, and host genetics. Here, we discuss MHC genetic associations reported in infectious diseases from GWAS (Table 2) and how these findings can explain increased susceptibility or protection by affecting human immune responses. This is why certain MHC classes are important in infectious diseases. We note that fewer MHC associations have been found for infectious diseases than for autoimmune diseases, mainly because of the smaller cohort sizes for infectious diseases. Thus, extensive fine-mapping studies (and imputation) have yet to be performed, with the exception of a few studies on infections such as human immunodeficiency virus (HIV) [62], human hepatitis B virus (HBV) [63, 64], human hepatitis C virus (HCV) [65], human papilloma virus (HPV) seropositivity [66], and tuberculosis [67].

From a genetic viewpoint, one of the best-studied infectious diseases is HIV infection. MHC class I loci have strong effects on HIV control [62, 68–71] and acquisition [72], viral load set point [69–71], and non-progression of disease [73] in Europeans [69, 70, 72, 73], and in multi-ethnic populations (Europeans, African-Americans, Hispanics, and Chinese) [62, 68, 71]. A GWAS of an African-American population indicated a similar HIV-1 mechanism in Europeans and African-Americans: about 9.6% of the observed variation in viral load set point can be explained by HLA-B\*57:01 in Europeans [69], while about 10% can be explained by HLA-B\*57:03 in African-Americans [68]. In contrast, the MHC associations and imputed amino acids identified in Europeans and African-Americans were not replicated in Chinese populations, possibly because of the varied or low minor allele frequencies of these SNPs in Chinese people [71]. A strong association to the MHC class I polypeptide-related sequence B (*MICB*) was also revealed by a recent GWAS for dengue shock syndrome (DSS) in Vietnamese children [74]. This result was replicated in Thai patients, indicating *MICB* can be a strong risk factor for DSS in Southeastern Asians [75].

HLA-DP and HLA-DQ loci, along with other MHC or non-MHC loci (TCF19, EHMT2, HLA-C, HLA-DOA, UBE2L3, CFB, CD40, and NOTCH4) are consistently associated with susceptibility to HBV infection in Asian populations [76–83]. Significant associations between the HLA-DPA1 locus and HBV clearance were also confirmed in independent East Asian populations [79, 81]. A fine-mapping study of existing GWAS data from Han Chinese patients with chronic HBV infection used SNP2HLA as the imputation tool and a pan-Asian reference panel. It revealed four independent associations at

**Table 2** Major histocompatibility complex (MHC) associations and risks for infectious diseases identified by genome-wide association studies (GWAS)

Phenotype	Initial sample size	Replication sample size	Mapped / nearest gene	SNPs	P-value	OR or beta	Reference

HLA-DP $\beta$ 1 positions 84–87, HLA-C amino acid position 15, rs400488 at HCG9, and HLA-DRB1\*13; together, these four associations could explain over 72.94% of the phenotypic variance caused by genetic variations [64]. Another recent study using imputed data from Japanese individuals indicated that class II alleles were more strongly associated with chronic HBV infection than class I alleles (Additional file 1) [63]. Similarly, the HLA-DQ locus influences the spontaneous clearance of HCV infection in cohorts of European and African ancestry, while DQB1\*03:01, which was identified by HLA genotyping together with the non-MHC IL28B, can explain 15% of spontaneous HCV infection clearance cases [65]. HLA-DQB1\*03 also confers susceptibility to chronic HCV in Japanese people [84]. A GWAS in a European population revealed that HPV8 seropositivity is influenced by the MHC class II region [85]. However, HPV type 8 showed a higher seropositivity prevalence than other HPV types at the population level [66]; this led to a limited power to detect associations with other HPV types. Fine-mapping using the same European population as in the GWAS [66] revealed significant associations with HPV8 and HPV77 seropositivity, but only with MHC class II alleles, not with class I alleles. This indicates a pivotal role for class II molecules in antibody immune responses in HPV infection. Notably in this study, imputation was performed using HLA\*IMP:02 and reference panels from the HapMap Project [86] and the 1958 British Birth Cohort, as well as using SNP2HLA with another reference panel from the T1DGC. Both imputation tools provided comparable results, thus highlighting the important role of MHC class II alleles in antibody response to HPV infection [66].

A GWAS on leprosy in Chinese populations pointed to significant associations with HLA-DR-DQ loci [87, 88]; these results were replicated in an Indian population [89]. Fine-mapping the MHC showed that variants in HLA class II were extensively associated with susceptibility to leprosy in Chinese people, with HLA-DRB1\*15 being the most significant variant [87]. HLA class II variants also influence the mycobacterial infection tuberculosis in European and African populations [67, 90]. Fine-mapping identified the DQA1\*03 haplotype, which contains four missense variants and contributes to disease susceptibility [67]. A meta-analysis showed that five variants (HLA-DRB1\*04, \*09, \*10, \*15, and \*16) increase the risk of tuberculosis, especially in East Asian populations, whereas HLA-DRB1\*11 is protective [91].

Using a population from Brazil, the first GWAS on visceral leishmaniasis revealed that the class II HLA-DRB1-HLA-DQA1 locus had the strongest association signal; this was replicated in an independent Indian population [92]. This common association suggests that Brazilians and Indians share determining genetic factors

that are independent of the different parasite species in these geographically distinct regions.

Finally, epistatic interactions between MHC class I alleles and certain KIR alleles (between KIR3DS1 combined with HLA-B alleles) are associated with slower progression to acquired immunodeficiency syndrome (AIDS) [93] and better resolution of HCV infection (between KIR2DL3 and its human leukocyte antigen C group 1, HLA-C1) [94].

### Insights into the biology of infectious diseases

Associations with the MHC class I locus suggest a critical role for CD8<sup>+</sup> T-cell responses in major viral infections such as HIV, dengue, and HCV. This critical role of CD8<sup>+</sup> T-cell responses in HIV infection is reflected by the slow disease progression seen in infected individuals because of their increasing CD8<sup>+</sup> T-cell responses that are specific to conserved HIV proteins such as Gap p24 [95]. Interestingly, five out of six amino acid residues (Additional file 1) identified as associated with HIV control [62] lie in the MHC class I peptide-binding groove, implying that MHC variation affects peptide presentation to CD8<sup>+</sup> T cells. In particular, the amino acid at position 97, which lies in the floor of the groove in HLA-B, was most significantly associated with HIV control ( $P = 4 \times 10^{-45}$ ) [62]. This amino acid is also implicated in MHC protein folding and cell surface expression [96]. An association found in severe dengue disease also underscores the role of CD8<sup>+</sup> T cells in disease pathogenesis: class I alleles that were associated with an increased risk of severe dengue disease were also associated with weaker CD8<sup>+</sup> T-cell responses in a Sri Lankan population from an area of hyper-endemic dengue disease [97]. In HCV, similar to the protective alleles against HIV infection [95], HLA-B\*27 presents the most conserved epitopes of HCV to elicit strong cytotoxic T-cell responses, thereby reducing the ability of HCV to escape from host immune responses [98].

Associations between genetic variants in the MHC class II region and disease susceptibility imply that impaired antigen presentation or unstable MHC class II molecules contribute to insufficient CD4<sup>+</sup> T-cell responses and, subsequently, to increased susceptibility to infections. For instance, the amino acid changes at positions of HLA-DP $\beta$ 1 and HLA-DR $\beta$ 1 in the antigen-binding groove that influence HBV infection may result in defective antigen presentation to CD4<sup>+</sup> T cells or to impaired stability of MHC class II molecules, thereby increasing susceptibility to HBV infection [64]. CD4<sup>+</sup> T-cell responses are also critical in mycobacterial infections, such as has been described for leprosy and tuberculosis [99, 100]. Notably, monocyte-derived macrophages treated with live *Mycobacterium leprae* showed three main responses that explain infection

persistence: downregulation of certain pro-inflammatory cytokines and MHC class II molecules (HLA-DR and HLA-DQ), preferentially primed regulatory T-cell responses, and reduced Th1-type and cytotoxic T-cell function [99]. Macrophages isolated from the lesions of patients with the most severe disease form, lepromatous leprosy, also showed lower expression of MHC class II molecules, providing further evidence that defective antigen presentation by these molecules leads to more persistent and more severe *M. leprae* infection [99].

Recently, it has been shown that CD4<sup>+</sup> T-cells are essential for the optimal production of IFN $\gamma$  by CD8<sup>+</sup> T-cells in the lungs of mice infected with *M. tuberculosis*, indicating that communication between these two distinct effector cell populations is critical for a protective immune response against this infection [101]. Impaired antigen processing and presentation from *Leishmania*-infected macrophages (which are the primary resident cells for this parasite) to CD4<sup>+</sup> T cells could explain increased susceptibility to leishmaniasis [102]. The association between HPV seropositivity and the MHC class II region also suggests that class II molecules bind and present exogenous antigens more effectively to a subset of CD4<sup>+</sup> T cells known as Th2. These Th2 cells help primed B lymphocytes to differentiate into plasma cells and to secrete antibodies against the HPV virus.

In support of the hypothesis that genetic effects on both CD8<sup>+</sup> (class I) and CD4<sup>+</sup> (class II) cells modify the predisposition to infections, it should be noted that some infectious diseases, such as HIV, HBV, HCV, and leprosy, show associations to more than one of the classic MHC classes and, in some cases, the associations differ between populations (Table 2). Moreover, consideration must be given to the differences between viral and bacterial genotypes in the same infection, which play a role in determining potentially protective effects. Overall, associations with multiple MHC loci reflect the complex and interactive nature of host immune responses when the host encounters a pathogen.

#### Relationship between the MHC variants involved in autoimmune and infectious diseases

Both autoimmune and infectious diseases seem to involve certain MHC classes (Fig. 2a), and only a few MHC alleles are shared between these two distinct disease groups (Fig. 2b). The identification of shared MHC variation has provided insight into the relationships between the MHC variants involved in autoimmune and infectious diseases and which have been uniquely shaped throughout human evolution [18].

Two hypotheses have been proposed to explain the relationships between the MHC variants involved in both groups of diseases. The first, known as the “pathogen-

driven selection” hypothesis, states that pressure exerted on the human genome by pathogens has led to the advantageous selection of host defense genes and, subsequently, to much higher polymorphism in the MHC. This polymorphism has contributed to the development of complex immune defense mechanisms that protect humans against a broad range of pathogens. Thus, heterozygosity at MHC loci is evolutionarily favored and has become an efficient mechanism contributing to the highly polymorphic MHC (the “MHC heterozygosity advantage”) [103]. Two examples of MHC heterozygote advantage are HIV-1-infected heterozygotes at class I loci, which are slower to progress to AIDS [104, 105], and HBV-infected heterozygotes at class II loci, which seem more likely to clear the infection [106]. In addition, human populations exposed to a more diverse range of pathogens display higher class I genetic diversity than those exposed to a smaller range [107]. However, the true effect of infectious diseases on selection might be underestimated because of the heterogeneity of many pathogens and the changing prevalence of infectious diseases over evolutionary time.

Positive selection of the advantageous effect of MHC polymorphism in infections may also be accompanied by a higher risk of developing autoimmune diseases. For example, the non-MHC locus *SH2B3* rs3184504\*A is a risk allele for CeD but has been under positive selection because it offers the human host protection against bacterial infections [108]. To investigate whether other genetic variants in the MHC show this opposite direction effect between autoimmune and infectious diseases (Fig. 2b), we compared SNPs and alleles in the MHC identified by GWAS and fine-mapping studies on autoimmune diseases (Table 1; Additional file 2) with those identified in infectious diseases (Table 2; Additional file 1). On the one hand, HLA-B\*27:05, which has one of the strongest associations to AS in the MHC ( $P < 1 \times 10^{-2000}$ ) [37] and is present in all ethnic groups, increases AS risk. On the other hand, it also has a protective effect against HIV infection, showing a nominal significant value of  $5.2 \times 10^{-5}$  [70]. The second example of opposite allelic effect is the association between the rs2395029\*G allele and susceptibility to psoriasis (OR = 4.1;  $P = 2.13 \times 10^{-26}$ ) [109] and AIDS non-progression ( $P = 9.36 \times 10^{-12}$ ) [69]. Located in the HLA complex P5 (HCP5), rs2395029 is a proxy for the HLA-B\*57:01 allele [69], the strongest protective allele against AIDS progression [110]. Non-progressors carrying the rs2395029\*G allele had a lower viral load than other non-progressors [73].

Another study showed that psoriasis patients carry the same genetic variants as HIV controllers/non-progressors and that they are particularly enriched for the protective allele HLA-B\*57:01 ( $P = 5.50 \times 10^{-42}$ ) [111]. Moreover, the intergenic variant rs10484554\*A, which is

in LD with HLA-C ( $r^2 \geq 0.8$ ), was significantly associated with AIDS non-progression ( $P = 6.27 \times 10^{-8}$ ) [73] and with susceptibility to psoriasis ( $OR = 4.66$ ,  $P = 4 \times 10^{-214}$ ) [58]. HLA-C\*06:02 (equivalent to HLA-Cw6) was most strongly associated with susceptibility to psoriasis ( $OR = 3.26$ ;  $P = 2.1 \times 10^{-201}$ ) [36] and is also protective against HIV infection ( $OR = 2.97$ ;  $P = 2.1 \times 10^{-19}$ ) [62]. The same allele has been associated with susceptibility to CD ( $OR = 1.17$ ;  $P = 2 \times 10^{-13}$ ) [46]. Interestingly, the role of MHC in HIV control also relates to the influence of MHC expression levels. For instance, rs9264942 shows one of the most significant genome-wide effects observed on HIV control [62, 69, 70]: it is located 35 kb upstream of the HLA-C locus (Table 2) and has been associated with high HLA-C expression, conferring protection against HIV infection [112]. Explaining this protective effect, HLA-C allelic expression was correlated with increasing likelihood of CD8<sup>+</sup> T-cell cytotoxicity [112]. However, the -35 SNP is not a causal variant, but is in LD with a SNP at the 3' end of HLA-C; this affects HLA-C expression by influencing binding of the microRNA Hsa-miR-148a [113]. Notably, high HLA-C expression has a deleterious effect by conferring risk for Crohn's disease [113]. The potential mechanism by

which HLA expression levels confer resistance to pathogens, and also lead to greater autoimmunity, could be through promiscuous peptide binding [114]. Lastly, HLA-DQB1\*03:02 showed a dominant risk effect for MS ( $OR = 1.30$ ;  $P = 1.8 \times 10^{-22}$ ) [45], whereas it is a resistant allele against chronic HBV infection ( $OR = 0.59$ ;  $P = 1.42 \times 10^{-5}$ ) [63].

The second hypothesis states that pathogens can trigger autoimmunity, as suggested by epidemiological studies [115, 116]. For example, it has recently been shown that apoptosis of infected colonic epithelial cells in mice induces the proliferation of self-reactive CD4<sup>+</sup> T cells that are specific to cellular and to pathogenic antigens [117]. Self-reactive CD4<sup>+</sup> T cells differentiate into Th17 cells, which promote production of auto-antibodies and auto-inflammation, implying that infections can trigger autoimmunity [117]. Other mechanisms have been proposed, such as molecular mimicry, bystander activation, exposure of cryptic antigens, and superantigens [118]. Common genetic signatures between autoimmune and infectious diseases indirectly imply that pathogens can indeed trigger autoimmunity. In line with this second hypothesis, we have identified common risk factors between autoimmune and infectious diseases, such as the

alleles: HLA-DRB1\*15 for MS, SLE (Table 1), and leprosy (OR = 2.11;  $P = 3.5 \times 10^{-28}$ ) [87]; rs9275572\*C, located in HLA-DQ, for chronic HCV infection (OR = 0.71;  $P = 2.62 \times 10^{-6}$ ) [84], and SLE ( $P = 1.94 \times 10^{-6}$ ) [119]; HLA-DQB1\*03:02 for MS (OR = 1.30;  $P = 1.8 \times 10^{-22}$ ) [45] and pulmonary tuberculosis (OR = 0.59;  $P = 2.48 \times 10^{-5}$ ) [67]; HLA-C\*12:02 for UC (OR = 2.25;  $P = 4 \times 10^{-37}$ ) [46], CD (OR = 1.44;  $P = 3 \times 10^{-8}$ ) [46], and chronic HBV infection (OR = 1.70;  $P = 7.79 \times 10^{-12}$ ) [63]; and rs378352\*T, located in HLA-DOA, for chronic HBV infection (OR = 1.32;  $P = 1.16 \times 10^{-7}$ ) [78] and RA (OR = 1.24;  $P = 4.6 \times 10^{-6}$ ) [25] (Fig. 2a).

Associations within the MHC region for several autoimmune diseases, such as RA, CeD, AS, T1D, Graves' disease, and DM, and HBV infection are driven by variants and alleles around HLA-DPB1 (Table 1), implying that viruses like HBV could trigger autoimmunity. Although there is no convincing evidence, HBV and HCV are associated with extra-hepatic autoimmune perturbations [120, 121]. Lastly, the DQA1\*03:01 allele, which contributes to tuberculosis susceptibility (OR = 1.31;  $P = 3.1 \times 10^{-8}$ ) [67], is also a well-known risk factor for CeD as part of the DQ8 (DQA1\*03-DQB1\*03:02) and DQ2.3 (trans-DQA1\*03:01 and DQB1\*02:01) haplotypes [122]. DQA1\*03 also increases susceptibility to T1D, RA, and juvenile myositis [123–125]. Overall, the direction of association is the same for most shared MHC class II loci, suggesting that bacteria and viruses can trigger immune responses. No viruses have been proven to cause an autoimmune disease thus far, but multiple virus infections could prime the immune system and eventually trigger an autoimmune response; this is a hypothesis that has been supported by animal studies on MS [126].

## Conclusions and future perspectives

We have discussed recent advances in understanding the genetic variation in the MHC in relation to autoimmune and infectious diseases. However, confidence in the associations between MHC and infectious diseases is limited, mainly because of the relatively small patient cohort sizes available. Further limitations to identifying and replicating associations with infectious diseases include: strain differences, heterogeneity in clinical phenotypes, use of inappropriate controls (such as individuals with asymptomatic infections), and population-specific differences in allele frequency and/or haplotype structure. Finally, with the exception of a few described above, no imputation has been performed in most infectious disease studies. In certain populations, such as Africans, lower LD makes it challenging to perform MHC imputation.

Although application of a traditional GWAS is challenging for infectious diseases, other approaches may increase the power of genetic studies. For instance, a combination of transcriptional analysis and systems

biology allowed the identification of a novel role for type I IFN signaling pathway in the human host immune response against *Candida albicans* [127]. The use of control subjects for whom it is known whether they clear the infection, and who come from the same hospital as patients, could be appropriate for infectious diseases so that co-morbidities and clinical risk factors are as similar as possible between groups. Overall, initiating collaborative efforts to increase patient cohort numbers, designing better studies by using more appropriate controls and more homogeneously clinically defined patient phenotypes, and applying imputation using population-specific reference genomes would open new avenues to study the genetics of infectious diseases.

In contrast to infectious diseases, the added value of fine-mapping the MHC to pinpoint genetic risk factors for autoimmune disease has been well demonstrated by numerous studies. The associations that have been found in both European and Asian populations to the same amino acids by fine-mapping the MHC suggest that the same molecular mechanism is involved, despite the differences in MHC allele frequencies seen between these ethnic groups.

MHC-based imputation approaches using genotype data, along with the use of population-specific reference panels for imputing MHC alleles and amino acids, has allowed identification of the MHC variation associated with complex diseases. Although identification is challenging, genetic variation in the MHC is of critical importance for two reasons. First, it sheds light on the development of autoimmunity, given the two hypotheses discussed above (pathogen-driven evolutionary selection of protective genes or pathogens as triggers of autoimmunity), and second, it yields greater understanding of the complexity of the human immune system. This knowledge will ultimately permit the design of better prophylactic and therapeutic strategies to achieve more balanced patient-immune responses during treatment.

## CHAPTER 6

### GENERAL DISCUSSION

#### • What We Learned From the Use of a Systems Genomics Approach in Candidaemia: From Genes to Potential Drug Targets

---

Traditionally, there are three major classes of antifungal drugs used for the treatment of *Candida* spp. bloodstream infections: 1) Triazoles (fluconazole, voriconazole), 2) echinocandins (caspofungin, micafungin, anidulafungin) and 3) polyenes (amphotericin B deoxycholate [AmB-d], liposomal amphotericin B [L-AmB], amphotericin B lipid complex [ABLC], and amphotericin B colloidal dispersion [ABCD]). The majority of these drugs target the cell wall (echinocandins) or the cell membrane (amphotericin, azoles) of the fungus<sup>1-3</sup>. Novel drug targets currently being investigated include glycosylphosphatidylinositol biosynthesis, histone deacetylases, and heat shock proteins<sup>4</sup>. However, it is important to mention that there is an alarming decrease in the development of antifungal drugs, with only five antifungal agents approved by the US Food and Drug Administration in the last 13 years<sup>5</sup>. One key fundamental challenge in the development of new antifungal drugs compared to other antimicrobials targeting bacteria is that fungal pathogens are more closely related to the human host, among other challenges that are discussed elsewhere<sup>6</sup>. Therefore, there is an urgent need to develop novel antifungal prophylactic or treatment strategies.

Given that individuals present considerable innate immune variation in host responses to candidaemia, ranging from extreme susceptibility to complete resistance and tolerance, host-directed therapies based on an individual's genetic make-up have a high probability of success. A recent study showed that drug mechanisms supported by genetic evidence would succeed twice as often as those without (from phase I to approval)<sup>7</sup>. In addition, a host-directed treatment may exert a weaker selection pressure on pathogens, potentially making it more difficult for a pathogen to evolve beyond the control of the host immune response. Thus, with the aim of selecting the best drug targets for designing more effective treatment strategies, our efforts should be directed at dissecting the genetic architecture of disease susceptibility and at understanding host-pathogen interactions in a more comprehensive way.

Given the complexity of host-pathogen interactions, conventional experimental approaches that study only individual molecular components (either of the host

or pathogen) cannot provide a comprehensive picture of these interactions. Thus, the integration of high-throughput multi-omics data (transcriptomics, proteomics, metabolomics, lipidomics, etc.), which can be used to prioritize genes for follow-up functional experiments to better understand their role in host immune defence and identify molecular pathways that underlie disease pathogenesis, is a necessity for advancing our understanding of host-pathogen interactions. These multi-omics data can be used to construct predictive models of the networks and dynamic interactions between the biological components that constitute the complex host-pathogen system. We followed this approach to prioritize the genes and identify the molecular pathways which underlie pathogenesis in *Candida* infections. Here we discuss directions that could be taken to develop new treatment strategies against candidaemia based on our findings (Fig.1).

In *chapter 2*, we demonstrated the potential of using a systems genomics approach to identify the genes and pathways that underlie susceptibility to candidaemia, ultimately prioritizing 31 genes enriched for the pathways inflammation, innate immunity, complement and hemostasis. Although the involvement of inflammation and innate immunity were expected findings, the identification of complement and hemostasis in candidaemia is novel. Given the vital role of the complement system in host immunity, and particularly in eliminating invading microorganisms, modulation of the complement system has been recognized as a promising strategy for drug discovery<sup>8</sup>. Thus, designing complement-specific drugs could be a promising strategy for candidaemia patients, and deserves further exploration.

A previously promising complement-specific drug target was one of our prioritized *cis*-genes, located in the candidaemia-associated locus, *PROC*. This gene was differentially expressed in response to *C. albicans* (Table 1, *chapter 2*). *PROC* encodes for protein C, which is known to reduce the clotting process, and its lack can lead to excess blood clotting<sup>9,10</sup>. This molecule had been previously targeted to treat sepsis, and the administration of recombinant activated protein C (APC) in sepsis patients had been suggested to increase the levels of protein C and ameliorate the patient outcome<sup>11</sup>. However, APC has also been associated with a higher risk of bleeding. In 2011, the European Medicines Agency withdrew Xigris® (human recombinant activated protein C), which was being produced by pharmaceutical company Eli Lilly, from the market and ongoing clinical trials were discontinued<sup>11</sup>. Although the use of APC was not successful for treating sepsis patients, our findings highlight the importance of blood coagulation processes during infection, particularly in candidaemia. However, it is worth keeping in mind that the biology of sepsis is complex, and not specific to infection, and success in developing new treatments will need stratification of patients based on genetic profiling so those with a high risk of sepsis will benefit most from the drug. Unless additional clinical trials provide evidence of a treatment effect based on genetic

**Fig.1. 1: Summary of main findings on susceptibility to candidaemia and potential directions to be taken for discovery of new antifungal drugs.**

Given the limited size of patient cohorts, the use of a population-based cohort provides a promising platform to generate pathogen-specific molecular data. In this work, we used peripheral blood mononuclear cells (PBMCs) isolated from healthy volunteers (500FG cohort) stimulated with *C. albicans* to profile gene expression (using RNA sequencing, chapter 2), cytokines (using ELISA, chapter 2 and 3), and 92 circulatory inflammatory proteins (OLINK technology, chapter 4) in response to *C. albicans*. In addition to these molecular data, we performed the first GWAS on candidaemia using our candidaemia cohort consisting of 178 patients and 175 case-matched controls (chapter 3). Pathway enrichment analysis of differentially expressed genes in response to *C. albicans* revealed complement and hemostasis as important molecular pathways underlying pathogenesis of *Candida* infection, together with innate immunity and inflammation (chapter 2). Using genetic and cytokine measurements from the 500FG cohort, we mapped cytokine-QTLs in response to *C. albicans*. Of note, 21 independent loci that modulate cytokine levels were found to be associated with candidaemia susceptibility, and these were enriched for lipid metabolism pathways (chapter 3). By integrating different molecular data (blue labels: genetics, transcriptomics, proteomics), we prioritized genes for follow-up with *in vitro* and *in vivo* functional experiments. Three examples of genes discussed in this thesis are *MAP3K8*, *SERPINA1* and *PROC*. To obtain a more comprehensive picture of *C. albicans*-host interactions in the future, it is essential to make use of currently available high-throughput technologies (as summarized in Table 1, chapter 1) to generate additional molecular data (gray labels: metabolomics, lipidomics) in response to *C. albicans*. Integration of multi-omics data should identify interesting gene candidates for functional experiments using the most appropriate *in vitro* and/or *in vivo* models. Finally, mycobiome studies could provide additional valuable information about how the mycobiome and dysbiosis of gut health contribute to susceptibility to candidaemia. Ultimately, these multi-omics data can be used to construct predictive models of the networks and dynamic interactions that control candida infection and pinpoint promising drug targets for further investigation aimed at developing novel effective antifungal drugs.

profiling, we should be aware and cautious of the benefits and harms of APC, and in general of new drug targets.

Early studies on developing protective antibodies (Ab) against experimental disseminated candidiasis in mice provided evidence that the mechanism of Ab protection is due to rapid and efficient complement deposition on the fungal cell surface, which leads to preferential uptake and killing by phagocytic cells<sup>12–14</sup>. In addition, mice with C5 deficiencies show decreased resistance in disseminated candidiasis<sup>15,16</sup>. To elucidate the role of the complement system in candidaemia, the use of animals with genetic deficiencies of individual complement components infected with *C. albicans* (such as C5-deficient mice and C6-deficient rats) would be particularly useful, as has been described for bacterial infections<sup>8,17,18</sup>. However, animal studies cannot completely represent the human situation. Thus, currently available proteomic technologies (mass spectrometry-based proteomics) are better suited to study the complement system to further understand fungal-host interactions. The recent development of a method of “mixed and quantitative proteome analysis”, in which *C. albicans* and macrophages were simultaneously analyzed by nanoscale liquid chromatography coupled to tandem mass spectrometry (nanoLC-MS/MS) without the need of isolation of the two individual living cells, provides new opportunities to study native interactions of *C. albicans* with macrophages (see Table 1, Chapter 1)<sup>19</sup>. NanoLC-MS/MS could be extended to additional immune cell types as regulation of the antifungal immune responses involves the coordinated contribution of different cell types.

Another interesting finding that needs further exploration as a potential therapeutic target is that we found that genetic variants associated with candidaemia susceptibility that influence cytokines upon *Candida* stimulation in peripheral blood mononuclear cells (PBMCs) are enriched for lipid and lipoprotein metabolism (chapter 3). This finding leads to the hypothesis that targeting host lipid synthesis and metabolism can potentially modulate cytokine responses and, subsequently, susceptibility to candidaemia. In general, inflammation and infections (by gram positive or negative bacterial, viral, tuberculosis) induce a variety of alterations in lipid metabolism that may initially dampen inflammation or fight infection, but which, if chronic, could contribute to the increased risk of atherosclerosis<sup>20</sup>. However, the exact mechanism by which inflammation and infection induce these lipid changes is still unclear. A hypothesis described by P.S.R.K. Sastry stated that the fungal infection could play a role in the development of atherosclerosis, which implies that *C. albicans* induces altered levels of lipids, but the mechanism by which this occurs is yet to be identified<sup>21</sup>. In line with this hypothesis, a recent study showed that fungi of the genus *Candida*, including *C. albicans*<sup>22</sup>, were identified in 31.9% of atherosclerotic plaques. Based on these results, the authors speculated that *Candida* spp are capable of inducing inflammation of the vascular wall, and these in turn can lead to the development of atherosclerosis<sup>22</sup>. In addition, hyperlipoproteinemia enhances susceptibility to acute disseminated *C. albicans* infection in low-density-lipoprotein-receptor-deficient

(*Ldlr*<sup>-/-</sup>) mice in contrast to gram-negative bacterial infections<sup>23</sup>. In these studies, deficient *Ldlr* mice showed an increased outgrowth of *C. albicans* in their organs and produced significantly more pro-inflammatory cytokines than control mice<sup>23</sup>. For the future, quantitative proteomics coupled with traditional enzymatic colorimetric methods for follow-up confirmation of plasma lipids in patients would be useful for evaluating the host proteome responses upon *Candida* infection. Such a proteomic study recently revealed important changes in cellular structure and lipid metabolism in septic patients, changes that are possible targets for future intervention in sepsis<sup>24</sup>.

In an attempt to further explore specific genes as potential drug targets, we validated the role of the *MAP3K8* (also known as *Tpl2*) gene in cytokine regulation in response to *Candida* stimulation (chapter 2). *MAP3K8* is located in one of the Immunochip-identified loci associated with candidaemia susceptibility, and encodes a member of the serine/threonine protein kinase family that has a critical role in innate immunity<sup>25,26</sup>. *MAP3K8* signalling has been studied primarily downstream of TLR4 signaling and *Tpl2*<sup>-/-</sup> mice are susceptible to bacterial sepsis<sup>26–28</sup>. The association of the *MAP3K8* gene with susceptibility to *Candida* infection is novel and, in chapter 2, we demonstrated using chemical inhibitors that *MAP3K8* modulates cytokine production in *Candida*-stimulated PBMCs. Another serine protease inhibitor that needs further exploration as a potential therapeutic target is  $\alpha$ 1-Antitrypsin (AAT), which is encoded by the gene *SERPINA1*. Several previous findings suggested that AAT has a potential protective role in host defence against various infectious diseases, including *Cryptosporidium parvum* infection, *Pseudomonas aeruginosa* lung infection in cystic fibrosis patients, and HIV-1 infection<sup>29–32</sup>. A recent proteomic study to identify both human serum proteins coating *C. albicans* cells and fungi surface proteins identified 13 proteins belonging to the serpin family, providing evidence that *SERPINA1* interacts with the host serum, and may therefore have a critical, as of yet unexplored, role in host immune defence upon *Candida* infection<sup>33</sup>.

*MAP3K8* and *SERPINA1* thus seem to be interesting gene candidates to prioritize for future *in vitro* and *in vivo* experiments. Over-expressing or knocking-out these genes in relevant immune cell lines or mice, while challenging, would shed more light on their role in immune defence against *Candida* infection. Interestingly, the development of a murine model for *SERPINA1* has been challenging due to the presence of *SERPINA1* paralogs in the murine genome and the possibility of an embryonic role for *SERPINA1*, which results in embryonic lethality<sup>34,35</sup>. However, CRISPR/Cas9 technology has now enabled the creation of a new full knock out *SERPINA1* mouse model with a normal lifespan as a model for emphysema, and this model could also be highly relevant for studying the impact of *SERPINA1* in susceptibility to *Candida* infections<sup>36</sup>.

In addition to working towards a new understanding of the genetics of susceptibility to candidaemia, we also investigated genetic variations that influence circulatory inflammatory proteins that could be used as potential biomarkers for *Candida* infection (*chapter 4*). Here we identified 10 novel genome-wide significant protein quantitative trait loci (pQTLs) that influence CCL4, MCP-1, VEGF-A, IL-8, MCP-2, MCP-3 and CXCL9 in *Candida*-stimulated PBMCs by performing genome-wide protein quantitative trait loci (pQTL) mapping. Intriguingly, none of the 10 genome-wide significant pQTLs strongly influence the expression of *cis*-genes, although most of them are intronic variants (or intergenic). However, we should keep in mind that there are multiple ways in which genetic variation can modulate the abundance of circulatory inflammatory proteins, such as regulation of translation and RNA editing, alternative splicing and protein release from the cell membrane. Of note, it has been shown that intronic SNPs within 200 base pairs of the splice junctions can have functional effects on splicing<sup>37</sup>.

In addition to susceptibility, in *chapter 4*, we investigated the genetic variation that influences patient survival. Mortality rates in candidaemia patients range from 30-60%, suggesting that person-to-person differences, including genetics, may influence patient survival. We therefore performed a within-case GWAS to identify genetic variants that determine patient survival<sup>38</sup>. Of note, in contrast to our hypothesis that pQTLs explain susceptibility and/or patient survival, we showed that pQTLs showed a poor enrichment for genetic variants associated with either susceptibility to candidaemia or patient survival. This finding suggests that the genetic contribution to circulatory inflammatory responses in response to *C. albicans* is largely independent of the genetic contribution to disease susceptibility and patient survival. Moreover, we identified a genome-wide locus at chromosome 1 associated with survival ( $P = 5 \times 10^{-8}$ ) that did not show any significant association with susceptibility to candidaemia ( $P = 0.097$ ). This is an interesting finding as it points to a different biology between disease susceptibility and patient survival that could provide new therapeutic opportunities for these two phenotypes.

To summarize, we followed a systems genomics approach to investigate genetics and molecular pathways that contribute to susceptibility to candidaemia (*chapter 2*). We also investigated which genetic variations contribute to the abundance of cytokines/circulatory inflammatory proteins upon *Candida* stimulation (*chapter 3 and 4*) and characterized variation that determines patient survival (*chapter 4*). Although there is still a long way to go to develop new antifungal drugs, we believe that the currently available technologies, together with advanced computational methods, promise exciting times in the field of systems genomics approaches to candidaemia.

---

## • Limitations, Challenges and Future Perspectives

---

Systems genomics approaches are providing new potentials to investigate genetics and molecular pathways underlying infectious diseases, including candidaemia. However there are still major limitations and challenges that apply not only to our studies on candidaemia but also to studies of other infectious diseases. First, all identified genetic associations should be validated in an independent cohort. However, this is not a possibility for most currently published associations for infectious diseases in the GWAS catalogue (<https://www.ebi.ac.uk/gwas/>). Independent cohorts are also not currently available for candidaemia, and the cohort we used is the largest candidaemia cohort available to date. In addition, GWAS on infectious diseases allows the identification of the most common polymorphisms, i.e. those showing a minor allele frequency (MAF) of at least ~5%.

In general, even in diseases where multiple loci have been identified by GWAS, the proportion of genetic variance that can be explained by all identified genetic associations is modest, often less than 20% of the total genetic variance estimated from twin studies<sup>39</sup>. This is because the individual associations identified by GWAS are generally of modest effect, with odds ratios of typically 1.1 to 1.5. This ‘missing’ heritability (the observation that loci detected by GWAS explain a small minority of the inferred genetic variance) may be explained by the presence of epistatic interactions (which we will discuss below) or structural variants, the search for which has met with little success so far<sup>39</sup>.

An alternative hypothesis to explain the missing genetic component is the presence of rare variants, which may have larger effect sizes on disease phenotype but present low frequencies that cannot be detected with available GWAS microarrays. Previous GWAS studies from the National Human Genome Research Institute GWAS catalogue (<https://www.ebi.ac.uk/gwas/>) identified variants with a risk allele frequency <5%, indicating that low frequency and/or rare variants contribute to diverse phenotypes related to infectious diseases (Table 1). For candidaemia, three genome-wide significant, low frequency genetic variants ( $P < 5 \times 10^{-8}$ ) identified by ImmunoChip array were previously reported as associated to susceptibility<sup>40</sup>, and we also reported several susceptibility variants of low frequency (between 1% and 5%) in *chapter 2* (Table 2). Thus, sequencing of just the exome of patients, composed of all the exons in the genome, would allow identification of these rare variants. Early studies using exon sequencing to identify rare variants in other infectious diseases were focused on *TLR4* gene in meningococcal disease and on five TLR genes on tuberculosis<sup>41,42</sup>. Both studies showed an excess of rare (and some more frequent) coding changes in patients compared to controls. Another recent study that discovered a susceptibility gene using exome sequenc-

ing and an extreme phenotype study design showed a strong association between presence of *DCTN4* missense variants (rs11954652, MAF=0.048, and rs35772018, MAF=0.0178) and susceptibility to both earlier and more severe *Pseudomonas aeruginosa* infection<sup>43</sup>.

**Table 1.** Studies on infectious diseases from GWAS catalogue that identified low frequency variants ( $0.01 < \text{MAF} < 0.05$ ) and rare variants ( $\text{MAF} < 0.01$ ). The effect of variants was predicted using the Ensembl Variant Effect Predictor (VEP) online tool<sup>70</sup>.

However, an argument can be made against focusing on exons because the majority of low frequency and/or rare variants that have been associated with the infectious diseases presented here, including candidaemia, are non-coding variants (intronic or intergenic) (Table 1 and 2). Interestingly, the majority of low frequency genetic variants associated with candidaemia susceptibility showed an intermediate effect, with an odds ratio (OR) between  $\sim 2$  and  $\sim 5$  (Table 2), as compared to low frequency variants associated to a number of immune-mediated diseases, which showed an OR between  $\sim 1.3$  and  $\sim 4$  (as extracted from GWAS catalogue, Table 3). In addition, infectious diseases such as influenza A (H1N1) infection, HIV-1 infection, tuberculosis and leprosy show a similar behavior to candidaemia, with low frequency variants showing an intermediate effect (or even as high as  $\sim 26$  for influenza) (Table 1). Thus future studies of the genetics of infectious diseases, including candidaemia, should detect low frequency and/or rare variants using genomic tools (such as genotype imputation), custom genotyping arrays, and whole-genome sequencing in combination with the statistical approaches used for testing associations between phenotypes and rare variants that have made the study of these variants possible<sup>44,45</sup>.

It is important to study the genetics of populations of different ethnicities, specifically those other than Europeans. This will provide both the opportunity to replicate already identified associations and a chance to identify new loci specific to the genetic background of a certain population. Moreover, the presence of gene-gene interactions (epistasis), which may mask the effect of certain genes on

**Table 3.** Studies on immune-mediated diseases from GWAS catalogue that identified low frequency variants ( $0.01 < \text{MAF} < 0.05$ ). The effect of variants was predicted using the Ensembl Variant Effect Predictor (VEP) online tool<sup>70</sup>.

disease outcome, makes it challenging to study the genetics of infectious diseases. This means it is also important to study epistatic interactions. Of note, a previous study showed that epistatic interactions in fruit flies greatly influence the variance in quantitative traits, or characteristics influenced by multiple genes<sup>46</sup>. Therefore, gaining insight into epistatic effects can be used to infer genetic networks affecting quantitative traits. Knowing how genes interact with each other, and the exact effect of a variant, is valuable information to advance discoveries in personalized medicine. We reviewed epistatic interactions in autoimmune and infectious diseases with a focus on the MHC locus in *chapter 5*.

Most of our molecular data have been produced in a mixture of immune cells, such as PBMCs, (*chapters 2, 3 and 4*) because they are an easily accessible cell system. However, PBMCs are a mixture of immune cells consisting of T cells, B cells, NK cells, and monocytes and they do not contain neutrophils, erythrocytes and platelets. Therefore, using only PBMCs may not reflect the full range of physiological responses in human. Additionally, the use of animal models could provide a useful setting to test the role of gene candidates in immune defence against *C. albicans*. Animal models have been widely used to study host-pathogen interactions in an attempt to mirror the pathophysiology of most diseases, but may not always faithfully mimic human disease due to inter-species variations<sup>47</sup>. Instead, to fill the gap between standard 2D cell culture and animal models, organoids have been widely used to model host-pathogen interactions<sup>48</sup>. One of the unique advantages of organoids is that they allow researchers to examine patient-specific responses to pathogens as they are derived from two sources: (1) pluripotent stem cells (PSCs) or (2) adult stem cells (ASCs) derived from patients<sup>48</sup>. However, organoids are heterogeneous in both shape and size, which may lead to inconsistent findings. One potentially innovative way to overcome such challenges is microengineered models of the functional units of human organs, known as ‘organs-on-chips’<sup>49</sup>. ‘Organ-on-chips’ technology offers the possibility to emulate kidney, liver, brain, lung, intestines, and heart on a chip while also simulating the micro-environment that cells actually need to behave as if they are in the human body. Thus, these mini-organs provide a good alternative to using animal models.

Given that an effective immune response depends on the proper activation, regulation, function, and interaction of immune cells with their micro-environment (which includes a range of stimuli and other cell types such as endothelial cells<sup>50</sup>), ‘organ-on-chips’ would allow the study of these interactions in a more dynamic environment that is comparable to human physiology. An artificial liver was recently developed using this technology to test its responses to hepatitis B virus (HBV) infection<sup>51</sup>. This liver-on-a-chip had similar biological responses, including innate immune and cytokine responses, to those seen in the human liver following infection with HBV, a demonstration of the potential of using this new

technology for studying host-pathogen interactions. For *Candida* infection, it has been observed that fungal burden changes with variable dynamics in the kidney, brain, spleen, and liver, and declines in all organs except for the kidney in a fatal mouse model of invasive candidiasis<sup>52</sup>. Thus it would be interesting to study organ-specific control of *Candida* using organ-on-a-chip technology to identify which cellular and molecular factors determine these differences between organs. Moreover, in the long run, these organs on chips will revolutionize the development of drugs in personalized medicine as custom chips (potentially created by using stem cells from an actual patient) that imitate a patient's unique biology would allow us to better predict how that patient will respond to specific drugs used to treat their infection<sup>53</sup>.

Another important aspect to consider in studying host-pathogen interactions is that we need to understand in which cell types the changes at transcriptomic, proteomic or metabolomic level occur upon infection. For this, single-cell methods of analyzing the transcriptome, proteome and metabolome will provide higher resolution that can pinpoint which cell types are the major players during infectious disease. Several immunological studies have already demonstrated the role of monocytes and neutrophils in clearing *Candida* infection<sup>54,55</sup>, however single-cell RNA sequencing may reveal new context-specific *Candida*-specific signatures and novel cell types that are involved in the complex immune response against the fungal pathogens. To identify regulatory networks that govern immune response during infection, ChIP-Seq, ATACseq and PRO-seq are the key technologies currently available (Table 1, chapter 1) to build these regulatory networks. Integration of molecular data generated by these technologies with results from assays that interrogate the status of DNA, RNA, proteins, lipids and metabolites should provide a more comprehensive picture of host-pathogen interactions. In the near future, we should direct our efforts at generating all these multiple layers of molecular information, which can then be used to construct predictive models for the development of specific therapeutics.

Another challenge in using a systems genomics approach in infectious diseases is the development of computational methods robust enough to handle and analyze all these large -omics data and building relevant models to predict disease outcome and/or drug targets given the complexity of the host-pathogen interactions. Of note, a systems genomics approach makes use of large different datasets which requires cooperation and communication among the diverse scientists involved in experimental design, sample preparation, high-throughput assays and analysis and integration of large datasets. Therefore, building bridges between diverse members of the scientific community is crucial to advancing our knowledge using a systems approach. Another urgent challenge is that we need to establish publicly available databases to store and share the ever-increasing pathogen-specific

-omics datasets. The ‘Systems Biology Program for infectious Disease Research’ consortium funded by the US National Institute of Health (NIH) represents an example of this direction; it provides experimental datasets, software tools, computational models, and research protocols through the four NIH centers’ and the National Institute of Allergy and Infectious Diseases websites (<http://www.niaid.nih.gov/labsandresources/resources/sb/Pages/default.aspx>)<sup>56</sup>.

We also need to raise awareness about the need to increase the numbers of people included in patient cohorts, which are the main sources for generating -omics datasets to answer our research questions. For this, the scientific community first needs to clearly communicate with patients the importance of this work and to share all the information needed to help participants make an informed decision about participation. Next we need a coordinated effort aimed at collecting samples from a hospital-based setting that feeds into an appropriate infrastructure for archiving all biological samples from donors for use in research (biobanking) and to define ways of ensuring the sustainability of biobanking. However, while collecting cohorts and samples may be feasible for infectious diseases with millions of patients such as HIV (the World Health Organization estimated there were 36.7 million people living with HIV at the end of 2016), this will be more challenging for relatively rare diseases like invasive *Candida* infections. This difference is reflected in the number of currently available cohorts for HIV-related research, which the Harvard University Center for AIDS Research (<https://cfar.globalhealth.harvard.edu/>) currently catalogues as 30, a number that is in sharp contrast to our candidaemia cohort which is both unique and the largest to date.

Further specific limitations in our studies include that fact that our transcriptomic experiments on *Candida*-stimulated PBMCs were performed at only two time points, 4 and 24 hours (*chapter 2*) even though gene transcription is a dynamic process through time. Thus we ideally need to capture gene transcription at more time points to capture early and late *Candida*-specific gene signatures. A recent transcriptomic study of neutrophils, the main effector cells in killing the fungus, stimulated with both morphotypes of *C. albicans*, showed that the strongest transcriptional responses was after 60 min, independent of the *Candida* morphotype<sup>57</sup>. In this study, the infection of neutrophils was studied after 15, 30 and 60 mins to represent different stages of *in vitro* infection: recognition and adhesion (15 min), early phagocytosis (30 min), and entire phagocytosis of yeast or wrapping of hyphae (60 min)<sup>57</sup>. Thus, as discussed earlier, we need to extend the transcriptomic studies to a single-cell level by using multiple time points that reflect different stages of infection to achieve higher resolution than using only PBMCs. Moreover, we performed our studies using heat-killed *C. albicans* yeast, which is fundamentally different from live *C. albicans*. In PBMC cultures, live *C. albicans* can suppress IL-17 production during anti-*Candida* host immune de-

fence<sup>58,59</sup>. This makes it difficult to delineate defence mechanisms upon live *C. albicans* stimulation, rendering heat-killing an unavoidable necessity in our studies. Another focus for future studies should be testing other medically relevant fungal species than *C. albicans*, such as *C. tropicalis*, *C. glabrata*, and *C. krusei*<sup>60</sup>.

In addition, given that *C. albicans* is part of the normal microbiome composition in the host's gastrointestinal tract, fungal microbiome (also known as the mycobiome) studies would provide an additional valuable layer of information for better understanding how the mycobiome contributes to candidaemia susceptibility. For instance, in a recent study using a murine oral candidiasis model, mice treated with *Pichia* spent medium showed significantly lower infection scores, fungal burden, and tongue epithelial damage, indicating these findings from mycobiome data can lead to potential novel antifungals<sup>61</sup>. Further questions that could be addressed in mycobiome studies would be how the mycobiome influences the immune system and whether genetic factors contribute to mycobiome composition. Studying the mycobiome, and particularly *C. albicans* within it, may lead to the discovery of new metabolic pathways and key steps that play an important function in the pathogen proliferation, hyphae formation and pathogenesis that are either absent in human or different enough from their human counterparts. These distinct pathways from the human host could be potential targets for the development of novel drugs that show a reduced toxicity in the host.

Moreover, understanding host-pathogen interactions could shed light on the potential role of infectious agents as triggers for autoimmune diseases (a hypothesis discussed in detail in *chapter 5*). It would be interesting to study whether an opportunistic infection, such as *Candida* infection, can contribute to the development of autoimmune diseases. A recent study, for example, found that translocation of a gut microbe, *Enterococcus gallinarum*, from the gut to the liver and other systemic tissues triggers autoimmune responses in a mouse predisposed to autoimmunity<sup>62</sup>. Another study showed a possible mechanism for how infections alter genetic risk to make some individuals more susceptible to inflammatory diseases. The study showed that a protein produced by the Epstein-Barr virus (EBNA2) interacts with nearly half of the genetic risk loci associated with lupus in Europeans<sup>63</sup>. This interaction may contribute to changes in gene expression that in turn increase an individual's chance of developing lupus<sup>63</sup>. Similar EBNA2-anchored associations exist in multiple sclerosis, rheumatoid arthritis, inflammatory bowel disease, Type 1 diabetes, juvenile idiopathic arthritis and celiac disease<sup>63</sup>. Lastly, it has been hypothesized that *C. albicans* may trigger celiac disease because the yeast protein Hwp1 presents sequence homology with the gluten protein gliadin, which is a known trigger for celiac disease<sup>64</sup>. Recent studies have observed humoral cross reactivity between Hwp1 and gliadin during celiac disease and *C. albicans* infection, which supports the hypothesis that *Candida* infection triggers onset of celiac

disease in genetically-susceptible individuals<sup>65</sup>.

With the aim of establishing large-scale host-fungi interactions networks on a systems-biology scale, an extended inference approach based on protein orthology and data on gene function was recently developed for *C. albicans* and *Aspergillus fumigatus* (*A. fumigatus*)<sup>66</sup>. This integrated network framework can serve as a basis for analyses of high-throughput host-fungi transcriptome and proteome data<sup>66</sup>. This newly developed framework highlights that there is an awareness of directing our efforts to generate and integrate multi-omics data to better understand host-fungi interactions, which is underestimated in literature compared to bacterial and viral interactions. To sum up, given the inherent complexity of the human immune response to encountering an invading pathogen such as *C. albicans*, a systems genomics approach seems appropriate and promising for furthering our knowledge of pathogen-host interactions. Ultimately, this knowledge will help us develop more effective strategies that modulate immune responses that can help patients better control and fight infections.

### • Concluding Remarks

Our studies allowed us a glimpse of the genetic architecture of candidaemia. We observed that the majority of low frequency genetic variants associated with candidaemia susceptibility (with a frequency between 1% and 5%) showed an intermediate effect (Fig. 2, Table 2). From an evolutionary perspective, we can assume that variants that increase disease susceptibility are deleterious to fitness, and should be selected against, with the consequence that susceptibility variants should be low frequency and/or rare<sup>67</sup>. In addition, considering that mutation rates are sufficiently high, selection cannot remove all deleterious variants, and those that have an intermediate/modest effect on fitness may reach allele frequencies of 1% or occasionally more<sup>67</sup>. Moreover, given that *Candida* infections are opportunistic infections, we can speculate that these infections have co-evolved with other more prevalent infectious diseases, complicating the process of how the architecture of the human genome has been shaped by opportunistic infections such as *Candida* infections. For instance, during the 1980's, the emergence of the highly variable and fast evolving retroviral pathogen, HIV-1, that progressively causes a failure of the immune system would potentially have allowed opportunistic infections, such as fungal infections, to take hold. Indeed, the rise of human fungal infections coincided largely with the onset of the AIDS pandemic of the 1980's (<https://ensia.com/features/19036/>). Of note, candidaemia appears to be common in HIV-infected patients, particularly in patients with advanced HIV disease<sup>68</sup>.

Overall, we can speculate that three theories can explain the genetic architecture

**Fig.2.** Allele frequency and effect sizes for genetic variants associated with candidaemia susceptibility.

Solid colored bars (not depicted to scale) show the allele frequencies and Odds Ratios (ORs) of genetic variants associated with candidaemia susceptibility as presented in Table 2. The colored labels at the bottom correspond to *cis*-genes in close proximity to susceptibility variants (in a window of 500 kb). Figure adapted from that of Manolio T.A. *et al*<sup>99</sup>.

of *Candida* infections. Theory 1 suggests that relatively common variants account for susceptibility. If common variants are of importance to susceptibility, an extension of our GWAS approach of analysis of larger sample sizes might be the best way to identify common variants that confer susceptibility to the disease. In contrast, theory 2 speculates that very rare mutations account for susceptibility, as in primary immunodeficiency diseases. Indeed, several primary immunodeficiencies that behave as monogenetic disorders were found to show an increased susceptibility to *Candida* infections<sup>69</sup>. Lastly, theory 3 suggests that many individually rare variants with incomplete penetrance account for the genetic component of candidaemia susceptibility. If rare variants account for most susceptibility, next-generation sequencing of ever larger human cohorts should allow identifica-

tion of rare variants that can explain susceptibility.

In summary, our studies have opened new opportunities to understand the genetic architecture of candidaemia susceptibility and to identify genetic variants, genes and pathways that are implicated in disease susceptibility. Importantly, we have provided preliminary evidence that systems genomics approaches like ours can be a useful tool for identifying novel risk genes and pathways for *Candida* infection, especially given that collection of large cohorts is difficult because invasive *Candida* infections are relatively scarce. Despite the challenges it presents, we acknowledge that a systematic integration of different layers of molecular data may be the only avenue to further our knowledge and understanding of the complex host-pathogen interactions that shape our human genome. Last, but not least, this ever-growing body of molecular data will play a critical role in the development of novel prophylactic and treatment strategies that target relevant genes and pathways to control and limit infectious diseases.

## 10 Take-home messages

1. The genetic architecture of infectious diseases, including candidaemia, seems to differ from that of non-infectious diseases (such as immune-mediated diseases), with low frequency variants showing an intermediate effect in infectious diseases (Fig. 2).
2. A systems genomics approach has the potential to obtain novel insights into the genetics and molecular mechanisms underlying disease pathogenesis in relatively rare infections such as candidaemia (*chapter 2*).
3. Hemostasis seems to be an important biological process involved in susceptibility to candidaemia (*chapter 2*).
4. Host cytokine responses, as induced by *C. albicans*, *A. fumigatus* and *C. neoformans*, are organized in a pathogen-specific manner (*chapter 3*).
5. Cytokine responses induced by *C. albicans* yeast and hyphae are very similar, suggesting that cytokine responses to these two morphotypes are regulated by similar genetic and non-genetic factors (*chapter 3*).
6. Genes located in loci associated with susceptibility to candidaemia that modulate cytokine levels upon *C. albicans* stimulation are enriched in lipid

and lipoprotein metabolic processes (*chapter 3*).

**7.** Our first GWAS on candidaemia identified a novel strong genetic association of candidaemia with polymorphisms in the *PLA2G4B* gene that encodes for the cytosolic phospholipase A2 protein (*chapter 3*).

**8.** By comparing SNPs and alleles in the MHC locus associated with autoimmune and infectious diseases, we observed alleles with opposite allelic effect, supporting the ‘pathogen-driven selection’ hypothesis, and alleles with common genetic signatures, indirectly supporting the second hypothesis that pathogens can trigger autoimmunity (*chapter 5*).

**9.** Genetic variants influencing levels of circulatory inflammatory levels (protein-QTLs) showed a poor enrichment for variants associated with candidaemia susceptibility and patient survival, implying a distinct genetic contribution between inflammatory responses, candidaemia susceptibility and patient survival (*chapter 6*).

**10.** Follow-up functional studies are essential to shed light on the role of genes and molecular mechanisms in host defence against *Candida* infection to better understand their potential as therapeutic targets.

## • Summary

---

Candidaemia is a bloodstream yeast infection caused by the opportunistic fungal pathogen *Candida albicans* (*C. albicans*). Given the limited arsenal of anti-fungal drugs, together with the emergence of drug resistance, *Candida* is now ranked the fourth most common cause of nosocomial infections<sup>1-4</sup>. However, not all at-risk patients will develop fungal disease, suggesting that inter-individual differences – both genetic and non-genetic factors – play a critical role in determining disease susceptibility. However, it is difficult to identify genetic factors using genome-wide association studies (GWAS) alone because of the limited size of candidaemia patient cohorts and use of inappropriate controls (such as individuals with asymptomatic infections). Given the complexity of human host-*C. albicans* interactions, we followed an integrative approach to obtain a comprehensive picture of these interactions. We integrated multi-omics data (genetics, transcriptomics and proteomics) to identify genes and molecular pathways that are implicated in the anti-*Candida* host immune response. To generate *Candida*-specific data in addition to our candidaemia cohort, we made use of larger population-based cohorts (the 500FG and Lifelines cohorts).

In *chapter 2*, we integrated genetic data from our candidaemia cohort (genotyped by the Immunochip platform) with gene-expression profiles generated upon *Candida* stimulation in peripheral blood mononuclear cells (PBMCs), *Candida*-induced cytokine production capacity in PBMCs (TNF $\alpha$ , IL-6 and IFN $\gamma$ ), and circulating concentrations of three pro-inflammatory cytokines (IL-6, IFN $\gamma$  and IL-8) in patient serum. Of note, prioritized genes from susceptibility loci were enriched for pathways such as complement and hemostasis, suggesting that the complement system has an important role in disease susceptibility. Given that the Immunochip platform covers 186 loci, we performed the first GWAS to date to identify novel *Candida* susceptibility loci (*chapter 3*). In addition to identifying susceptibility loci, we investigated whether susceptibility can be explained by modulating cytokine levels. To this end, we made use of genetic data and measurements of six cytokines (IL-6, TNF $\alpha$ , IL-1 $\beta$ , IL-17, IL-22 and IFN $\gamma$ ) generated from the 500FG cohort, and mapped the genetic variation that influences cytokine levels in response to *C. albicans*. Interestingly, we observed that susceptibility variants that influence cytokines upon *Candida* stimulation in PBMCs are enriched for lipid and lipoprotein metabolism, suggesting a link between lipid metabolism and inflammation in *Candida* infection. Next, we systematically explored the inflammatory proteins released in candidaemia patients versus healthy individuals by profiling 92 inflammatory proteins in plasma from patients and healthy individuals from the Lifelines cohort (*chapter 4*). In addition to non-genetic factors, we studied the effect of host genetics on the regulation of inflammatory responses by mapping genetic variation that regulates *Candida*-specific inflammatory pro-

teins (protein-QTLs) in a joint analysis of the 500FG and Lifelines DEEP cohorts. Furthermore, we investigated whether pQTLs determine susceptibility to candidaemia and patient survival. We showed a poor enrichment of pQTLs for variants associated to either susceptibility to candidemia or patient survival, which implies a distinct genetic contribution between inflammatory responses, disease susceptibility and patient survival. Lastly, we reviewed advances in laboratory-based and computational approaches for mapping genetic variation in the major histocompatibility complex (MHC) locus, which has been a known risk factor for complex diseases, and discussed the relationship between the MHC variants involved in autoimmune and infectious diseases (*chapter 5*). By comparing SNPs and alleles in the MHC locus associated with both groups of diseases, we observed alleles with opposite allelic effect, supporting the ‘pathogen-driven selection’ hypothesis, and alleles with common genetic signatures, indirectly supporting the second hypothesis that pathogens can trigger autoimmunity.

In summary, we followed a systems genomics approach to investigate genetics and molecular pathways that contribute to susceptibility to candidaemia. Although there is still a long way to go to develop new drugs, including antifungals, we believe that the currently available technologies, together with advanced computational methods, promise exciting times in the field of systems genomics approaches, not only to candidaemia, but also to other infectious diseases. Although there are still challenges to face before fully embracing genomics in a clinical setting, and challenges to fully unravelling the true risks of disease remain, stratification of patients based on their genetic profile is a promising route toward designing host-directed therapies that would be more effective than the currently available traditional therapeutic approaches.

## • Samenvatting

Candidaemia is een schimmel infectie in de bloedbaan die veroorzaakt wordt door de opportunistische schimmel pathogeen *Candida albicans* (*C. albicans*). *Candida* staat nu als vierde op de ranglijst voor de meest voorkomende ziekenhuisinfecties, mede door het beperkte repertoire aan anti-schimmel medicatie en nieuw ontwikkelde resistenties tegen medicatie door de pathogeen. Niet iedereen met risico op *Candida* infectie ontwikkelt deze ook daadwerkelijk. Dit suggereert dat verschillen tussen individuen, genetisch of niet-genetisch, een kritische rol spelen in hoe ontvankelijk een persoon is voor candidemia. Het zoeken naar deze factoren wordt bemoeilijkt omdat het lastig is om de genetische factoren voor candidemia ontvankelijkheid te bepalen door een genoomwijde associatiestudie (GWAS), vanwege de beperkte hoeveelheid beschikbare patiënten en het vinden van een gepaste controle groep (zoals individuen met asymptomatische infecties). De complexiteit van de interacties tussen mens en *C. albicans* leidde ons ertoe om een integratieve aanpak te kiezen in het vinden van een duidelijk beeld naar al deze interacties. We hebben multi-omics data (genetica, transcriptoom en proteoom) geïntegreerd om genen en moleculaire pathways te vinden die geïmpliceerd zijn in de immuun respons tegen *Candida*. Om data te genereren die specifiek voor *Candida* is naast ons candidemia cohort, hebben we ook gebruik gemaakt van grotere populatie gebaseerde cohorten (500FG en Lifelines).

In *hoofdstuk 2* integreerden we genetische data van ons candidemia cohort (gegenotypeerd met het Immunochip platform) met genexpressie profielen gegenereerd na *Candida* stimulatie in 'peripheral blood mononuclear cells' (PBMCs), alsook cytokine productie capaciteit in PBMCs na *Candida* inductie (TNF $\alpha$ , IL-6 en IFN $\gamma$ ) en circulerende concentraties van drie pro-inflammatoire cytokinen (IL-6, IFN $\gamma$  en IL-8) in het serum van patiënten. De genen die geprioriteerd waren uit de loci waren verrijkt in complement en hemostase pathways. Dit suggereert dat het complement systeem een belangrijke rol speelt in candidemia ontvankelijkheid. Het Immunochip platform bestrijkt 186 loci over het genoom, wat ons toeliet om de eerste GWAS te doen en hiermee nieuwe genetische loci voor candidemia susceptibiliteit in kaart te brengen (*hoofdstuk 3*). Naast het identificeren van deze loci, hebben we gekeken of ontvankelijkheid verklaard kan worden door verschillen in cytokine concentraties. Hiervoor hebben we genetische data en metingen van 6 cytokinen (IL-6, TNF $\alpha$ , IL-1 $\beta$ , IL-17, IL-22 en IFN $\gamma$ ) uit het 500FG cohort gecombineerd, om de genetica van cytokine concentraties die te maken hebben met *C. albicans* in kaart te brengen. De varianten die cytokine concentraties veranderen na *Candida* stimulatie in PBMC zijn verrijkt voor lipide en lipoproteïne metabolisme. Dit toont een potentiële link tussen lipide metabolisme en ontstekingsreacties in *Candida* infecties. Hierna hebben we systematisch verkend welke ontstekings eiwitten vrijgegeven worden in candidemia patiënten,

ten opzichte van gezonde individuen. Hiervoor hebben we 92 ontstekings eiwit concentraties geprofileerd uit het plasma van patiënten en gezonde individuen in het lifelines cohort (*hoofdstuk 4*). Naast deze niet-genetische factoren hebben we de genetische factoren van de menselijke gastheer bestudeerd in zijn regulatie van ontstekingsreacties, door de genetische loci in kaart te brengen die *Candida* specifieke ontstekingseiwitten reguleren (pQTL), gecombineerd in twee cohorten: 500FG en Lifelines DEEP. In een verdiepende stap hebben we onderzocht of deze pQTL de ontvankelijkheid voor candidaemia verklaren. pQTL zijn niet verrijkt voor ontvankelijkheid voor candidaemia of overlevingskansen van een patiënt. Dit toont dat er waarschijnlijk genetische verschillen bestaan tussen inflammatoire respons en ontvankelijkheid voor en overlevingskansen tijdens candidaemia. Als laatste geven wij een review over de voortgang in laboratorium-gebaseerde en computationele methoden in het in kaart brengen van de genetische regulatie van het 'major histocompatibility complex' (MHC) locus (*hoofdstuk 5*). Het MHC locus is namelijk een bekende risico factor voor complexe ziekten. Hier bespreken we de relatie tussen MHC varianten in autoimmuun- en infectieziekten. Door SNPs en allelen in het MHC locus te vergelijken die met beide typen ziekten geassocieerd zijn. Wij vinden dat allelen tussen deze typen ziekten vaak tegengestelde effecten hebben, wat in lijn is met de 'pathogen-driven selection' hypothese. Wij vinden ook allelen met veel voorkomende genetische handtekeningen. Wat ook in lijn is met de tweede hypothese dat pathogenen autoimmunitet kunnen veroorzaken.

Samenvattend hebben wij systeem genetica technieken toegepast om genetica en moleculaire pathways te onderzoeken die te maken hebben met de ontvankelijkheid van candidaemia. Hoewel er nog een lange weg te gaan is voordat we nieuwe medicatie te kunnen ontwikkelen, waaronder nieuwe anti-schimmel infectie medicatie, geloven wij dat de technieken die nu beschikbaar zijn, gecombineerd met geavanceerde computationele methoden, de belofte hebben van veel succes in het systeem genetica veld. Niet alleen met betrekking tot candidaemia, maar ook tot andere infectie ziekten. Er zijn nog veel uitdagingen totdat genomics in de klinische setting toegepast kan worden, alsook het volledig begrijpen van ziekte risico, Maar nu al is het mogelijk om patiënten op te delen aan de hand van hun genetische profiel, om zo gastheer-specifieke behandeling te creëren die effectiever is dan de nu gebruikte traditionele therapie.

## • Acknowledgements

---

I started my PhD research in September 2014 and submitted my PhD book at the end of June 2018. The past years have flown by so fast, and I now find myself writing the last part of this book. Here I want to acknowledge all the people without whom none of my projects would have been possible and without whom I would have not grown to the scientist and person that I am today. It is hard to express my acknowledgement as it is sometimes beyond words.

First and foremost, I would like to thank the members of my thesis assessment committee, Prof. dr. Ingrid Molema, Prof. dr. Hanneke Oude Elberink and Prof. dr. Reinout van Crevel, for carefully reading and evaluating my thesis.

### **Department of Genetics**

I would like to thank my promotor, supervisor and mentor, Cisca Wijmenga, for her support and guidance, and for letting me take on challenges and opportunities to complete this research. Every question you asked me during all our meetings opened up new horizons for me to take the research further, to learn (..and learn), and motivated me day-by-day up to this moment. I am so thankful for this. I am also honored that I had the opportunity to attend special events of your life, the awarding of your Spinoza prize, your inauguration to the Lodewijk Sandkuijl Endowed Chair at University Medical Center Groningen, and your highly distinguished appointment of the Knight of the Order of the Netherlands Lion, just to name a few. I'm also thankful for happy moments we shared, such as visits to your house and barbeques with the group. Once again, thank you for giving me the opportunity to join your group and all your direction throughout these years. I wish you all the best in the years to come!

Dear Vinod, you have been a great co-promotor, supervisor and mentor. I cannot thank you enough for giving me the opportunity to work on the genetics of infectious diseases and to turn to bioinformatics during my PhD research. You trusted me and believed that I could manage all challenges. You let me learn and grow as a scientist (and as a person) under your daily supervision and guidance. I wish you all the best in your life!

I would also like to thank Iris. Thank you for supporting me from the beginning of my journey in genetics, for all your feedback, for encouraging me to be more confident, and for taking me to the lab and showing me all your magic on the lab bench. I know that I quit the lab along the way, but you are a great, supportive teacher and person. Always smiling! I wish you the best in your life. Dear Sebo, my research had nothing to do with celiac disease or lincRNAs, but thank you for all feedback, talks and guidance during our meetings. Also, thank you for all fun

group gatherings in your house. All the best in your life!

I would also like to thank the friends and colleagues whose contribution and feedback was invaluable for completing this thesis. Dear Yang, thank you for all the analyses, feedback and advice on how to move on through our challenges, and all the talks throughout these years. Dear Serena, thank you very much for your feedback and tips when needed. I would also like to thank all members of our PhD 'celiac' group: Aarón, Adriaan, Chan, Esteban, Ineke, Joram, Kieu, Maria, Raúl, Renée, Roeland, Olivier and Xiaojing. You are all very nice people and I am very happy and lucky that I met you. Thank you for your input on my projects during our meetings and our talks in the Department and outside of it. You are all great young scientists and I wish you the best in your next steps!

Of course, our work would not have completed without the contribution of the people in our laboratory. Dear Mathieu, Jody, Astrid and Rutger, thank you all so much for your help and little talks throughout these years, Outside the lab, the support from our lovely editors, Jackie and Kate, was also invaluable, Thank you very much both for making our research appropriately readable to the scientific world, including this thesis book! Thank you for all your tips on our writing and on presenting our data, knowledge that I will take with me in the years to come. I cannot thank you enough.

Dear Sasha, thank you for writing, with Cisca and Vinod, the review of this thesis. You were one of the first people that I met in this department as a master's student and one of the inspiring people who motivated me to join the department. I would also like to thank Jingyuan Fu for the data she provided and Lude Franke, Monique and Dylan for our meetings on single-cell sequencing. This list could keep growing forever (Annique, Urmo, Niek, Patrick, Pieter, Alex, Isis...) but, sincerely, I thank all the members of the Department of Genetics for the feedback during my presentations, our daily talks and their contribution to completing this thesis. It was great being member of this group and we can now celebrate the completion of this thesis.

Last but not least, I would like to thank Prof. Jan-Maarten van Dijl from the Department of Medical Microbiology, who invited me to do an internship in his group in August 2011, and encouraged me to apply for the TopMaster in Medical and Pharmaceutical Drug Innovation of the University of Groningen. If I had not applied, I would not probably be in that position today. Thank you for the support.

### **Collaborators**

It goes without saying that research is a collaborative effort, and the contribution of each and every one is so valuable for taking each step and gaining a better un-

derstanding on your research questions. I would like to thank our collaborators from the Radboud University whose contribution was significant in doing our research. Mihai Netea, Leo A.B. Joosten, Martin Jaeger, Mark S. Gresnigt, Rob Ter Horst, Marije Oosting, Sanne P. Smeekeens, Frank L. van de Veerdonk, Bart Jan Kullberg, thank you all for your contribution! Martin, thank you for all feedback and all the functional experiments that you performed throughout these years. In addition, a thank you to our collaborators from the Duke University Medical Center in North Carolina (United States of America), Melissa D. Johnson and John R. Perfect. Importantly, I would also like to thank all the patients and healthy volunteers who kindly donated blood samples so we were able to perform all the studies described in this thesis.

### **Family and Friends**

Completing a thesis takes a lot of time and hard work and, of course, friends to keep you busy and happy when you are not working. I have made great friends during these years in Groningen, both inside and outside of our Department, which makes it difficult for me to fit you all in these lines. Some of you may not be in Groningen any more, but I am thankful that I met you all and you are my friends. Isis, Mamen, Luz and Mireia, you are special ladies, and it was great spending time together. Mireia and Luz, thank for hosting me in Sabadel and Madrid so I had the chance to explore the wonderful cities of Barcelona, Madrid and surroundings. Maria and Andres, thank you for all our talks and Maria for listening to me during our breaks and walks in the city. Dear Kieu, thank you for all the moments we spent together inside and outside the office. Raul, thank you so much for helping me out with any bioinformatic challenge that I came up, at any time, and for our talks. I wish you all the best with Lilly. Lilly, you are very sweet person and it was great meeting you. Arnau, you also taught me some bioinformatics tricks and I cannot thank you enough for your patience. Thank you for being there when my bike was broken, when I had to move, and for everything. Dear Werna, you are a great and fun person, and I am happy that I met you! Thank you for all our talks, dinners and helped me out with moving (together with Arnau). David, thank you for being part of my life, and the trip to Africa. Dear Nshunge, you are like the sister that I did not have. No matter where we are, you will be always in my heart! I know that I have gained a second family by meeting you. Eleni and Mark, I wish you all the best in your life and with your lovely kids, Elisa and Rik. Last but not least, I would like to thank my dear friends back in Greece. We have been together for so many years and have shared so many moments and, even though I am not in Greece any more, you always make me feel the same way I did back in the day. Aunt Roula, thank you for all the walks, talks and laughs especially, every time I came back to Greece for a while.

The last paragraph is dedicated to my family, my mother, father and brother. I

know that you have been missing me every single day, but I know that you are happy when am happy. I feel it is not enough to thank you in a few lines but, any step I made in my life, including the completion of this thesis, is also thanks to you! Aggele, thank you for helping me out to turn this work into a book and for designing my cover! You have done a great job!

Thank you all from the bottom of my heart (including to those whose names were missed in these lines)!

---

## • Curriculum Vitae

---

Vasiliki (Vicky) Matzaraki was born in Xanthi, Greece. In 2002 she graduated from high school, passed the High School Exit Examination and was accepted to the Department of Molecular Biology and Genetics of the Democritus University of Thrace in Alexandroupolis, Greece. She graduated with a Bachelor in Molecular Biology and Genetics and continued her studies at the Department of Chemistry of the National and Kapodistrian University of Athens in Greece, where she obtained a Master's degree in Clinical Chemistry (2007-2009). During the second year of her master studies, she joined the Department of Hygiene, Epidemiology and Medical Statistics of the University of Athens Medical School, where she performed epidemiological studies on Human Immunodeficiency Virus (HIV)-1. In 2011, she was awarded an Abel Tasman Talent grant offered by the Graduate School of Medical Sciences of the University of Groningen (the Netherlands), and joined the Molecular Bacteriology Laboratory of the Department of Medical Microbiology of the University Medical Center Groningen (UMCG) for a short internship. During this internship, she studied the expression of surface-exposed proteins of the bacterium *Staphylococcus aureus*.

In 2012, she was accepted to the TopMaster programme Medical and Pharmaceutical Drug Innovation of the Faculty of Medical Sciences of the University of Groningen. During her master studies, Vicky did an internship in the Molecular Bacteriology Laboratory of the Department of Medical Microbiology of the UMCG, where she continued studying the molecular mechanism of staphylococcal spreading motility (January–June 2013). In addition to this, she later joined the Single Molecule Biophysics Laboratory of the Zernike Institute for Advanced Materials of the University of Groningen, where she focused on the kinetic characterization of viral fusion using influenza virus as a model (November 2013–May 2014). She graduated with distinction (*cum laude*) from the TopMaster programme in July 2014 and was awarded a grant from the Graduate School of Medical Sciences to support her three-year PhD research.

In September 2014, she started her PhD research under the supervision of Prof. Cisca Wijmenga and Dr. Vinod Kumar in the Department of Genetics of the UMCG, studying the genetics of infectious diseases with a focus on the bloodstream yeast infection known as candidaemia. During her PhD studies, Vicky was awarded a grant by the Stichting De Cock Foundation to perform functional studies. After completing her PhD, she will start her postdoc research in the group of Prof. Mihai Netea at the Radboud University in Nijmegen, the Netherlands.
